In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV
(cefotetan disodium)

P, 24, 798

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

Title page
Abstract and key words
Text
Acknowledgments
References
Tables: each table, complete with title and footnotes, on a separate page
Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

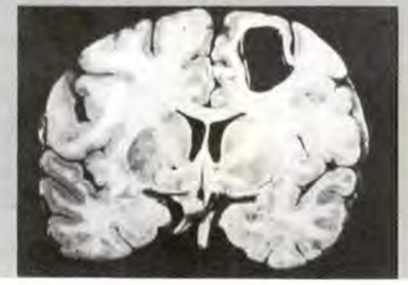
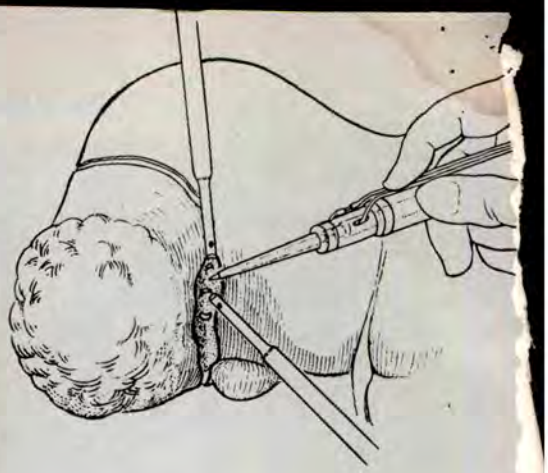
Now...the new book that shows you the role of surgical resection in the curative treatment of metastatic cancer





SURGICAL TREATMENT of METASTATIC CANCER

Edited by Steven A. Rosenberg, M.D., Ph.D.

Chief of Surgery, National Cancer Institute, Bethesda, MD.

9 contributors.

> *"For many patients with isolated visceral metastases from solid tumors, surgical resection of those metastatic deposits represents the best opportunity for cure. For patients with solitary pulmonary and hepatic metastases, up to 30% of patients may experience prolonged disease-free survival after metastasectomy. Only a small subset of patients with metastatic cancer are likely to benefit from surgical resection and identification of these patients is an important part of the application of this treatment."*
>
> **—from the *Preface***

Taking a bold approach to treatment

Now, for the first time, here is an in-depth resource that describes the role of surgical resection in the treatment of metastatic cancer. Editor Dr. Steven A. Rosenberg, Chief of Surgery at the National Cancer Institute, and a leading figure in cancer research and treatment, poses the premise that the role of surgical resection in treating metastatic cancer has indeed been underappreciated. He and a distinguished group of contributors have designed this book to present the essential information oncologists and surgeons need to understand the value of this treatment.

Presenting a highly significant option

Detailed information is presented concerning:

- the modern understanding of the biology of the metastatic process
- up-to-date techniques for the diagnosis of lung, liver, and brain metastases
- indications for and results of the surgical resection of lung, liver, and brain metastases
- the indications for lymph node dissection in the treatment of cancer.

about 304 pages. 120 illustrations. 68 tables. 1987. $59.50

vicodin® CIII

hydrocodone bitartrate 5 mg (Warning: May be habit forming.)
with acetaminophen 500 mg

INDICATIONS AND USAGE: For the relief of moderate to moderately severe pain.

CONTRAINDICATIONS: Hypersensitivity to acetaminophen or hydrocodone.

WARNINGS

Drug Abuse and Dependence: VICODIN is subject to the Federal Controlled Substances Act (Schedule III). Psychic dependence, physical dependence and tolerance may develop upon repeated administration of narcotics; therefore, VICODIN should be prescribed and administered with the same caution appropriate to the use of other oral-narcotic-containing medications.

Respiratory Depression: At high doses or in sensitive patients, hydrocodone may produce dose-related respiratory depression by acting directly on brain stem respiratory centers. Hydrocodone also affects centers that control respiratory rhythm, and may produce irregular and periodic breathing.

Head Injury and Increased Intracranial Pressure: The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a preexisting increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may 'obscure the clinical course of patients with head injuries.

Acute Abdominal Conditions: The administration of narcotics may obscure the diagnosis or clinical course of patients with acute abdominal conditions.

PRECAUTIONS

Special Risk Patients: VICODIN should be used with caution in elderly or debilitated patients and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, prostatic hypertrophy or urethral stricture.

Information for Patients: VICODIN, like all narcotics, may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery; patients should be cautioned accordingly.

Cough Reflex: Hydrocodone suppresses the cough reflex; caution should be exercised when VICODIN is used postoperatively and in patients with pulmonary disease.

Drug Interactions: The CNS-depressant effects of VICODIN may be additive with that of other CNS depressants. When combined therapy is contemplated, the dose of one or both agents should be reduced. The use of MAO inhibitors or tricyclic antidepressants with hydrocodone preparations may increase the effect of either the antidepressant or hydrocodone. The concurrent use of anticholinergics with hydrocodone may produce paralytic ileus.

Usage in Pregnancy: Pregnancy Category C. Hydrocodone has been shown to be teratogenic in hamsters when given in doses 700 times the human dose. There are no adequate and well-controlled studies in pregnant women. VICODIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Babies born to mothers who have been taking opioids regularly prior to delivery will be physically dependent. The intensity of the syndrome does not always correlate with the duration of maternal opioid use or dose.

Labor and Delivery: Administration of VICODIN to the mother shortly before delivery may result in some degree of respiratory depression in the newborn, especially if higher doses are used.

Nursing Mothers: It is not known whether this drug is excreted in human milk; therefore, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Central Nervous System: Sedation, drowsiness, mental clouding, lethargy, impairment of mental and physical performance, anxiety, fear, dysphoria, dizziness, psychic dependence, mood changes.

Gastrointestinal System: Nausea and vomiting may occur; they are more frequent in ambulatory than in recumbent patients. Prolonged administration of VICODIN may produce constipation.

Genitourinary System: Ureteral spasm, spasm of vesical sphincters and urinary retention have been reported.

Respiratory Depression: (See WARNINGS.)

DOSAGE AND ADMINISTRATION: Dosage should be adjusted according to the severity of the pain and the response of the patient. However, tolerance to hydrocodone can develop with continued use, and the incidence of untoward effects is dose related. The usual dose is one tablet every six hours as needed for pain. (If necessary, this dose may be repeated at four-hour intervals.) In cases of more severe pain, two tablets every six hours (up to eight tablets in 24 hours) may be required.

knoll®

Freedom from pain

Just one part of pain relief therapy.

Vicodin® provides greater patient acceptance

COMPARATIVE PHARMACOLOGY OF THREE ANALGESICS

	CONSTIPATION	RESPIRATORY DEPRESSION	SEDATION	EMESIS	PHYSICAL DEPENDENCE
HYDROCODONE		X			X
CODEINE	X	X	X	X	X
OXYCODONE	XX	XX	XX	XX	XX

Blank space indicates that no such activity has been reported.

Table adapted from Facts and Comparisons (Nov.) 1984 and Catalano RB. The medical approach to management of pain caused by cancer. "Semin Oncol" 1975; 2; 379-92 and Reuler JB, et. al. The chronic pain syndrome: misconceptions and management. "Ann Intern Med" 1980; 93; 588-96.

◆ Vicodin offers: less nausea, less sedation, less constipation.

...and longer lasting pain relief– up to 6 hours.

◆ Vicodin contains hydrocodone not codeine. In one study, 10 mg. of hydrocodone alone was shown to be as effective as 60 mg. of codeine.[1]

◆ In a double-blind study, Vicodin (2 tablets), provided longer lasting pain relief than 60 mg. of codeine.[2]

Plus...

◆ Vicodin offers the convenience of CIII prescribing.

◆ Dosage flexibility–1 tablet every 6 hours or 2 tablets every 6 hours (up to 8 tablets in 24 hours).

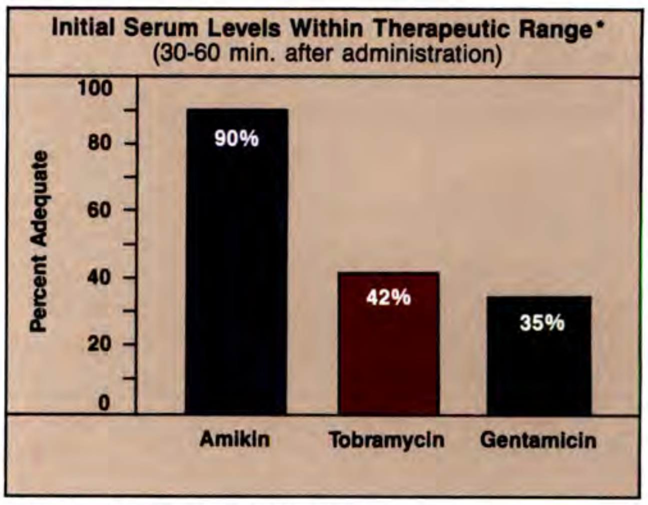
IN EMPIRIC THERAPY OF NOSOCOMIAL INFECTIONS

Peace of mind. Right from the start.

When infection develops in the hospitalized patient, there's no time to be wrong. Amikin® (amikacin sulfate) delivers the aggressive First-Dose therapy that can save lives.

First-Dose Predictability.

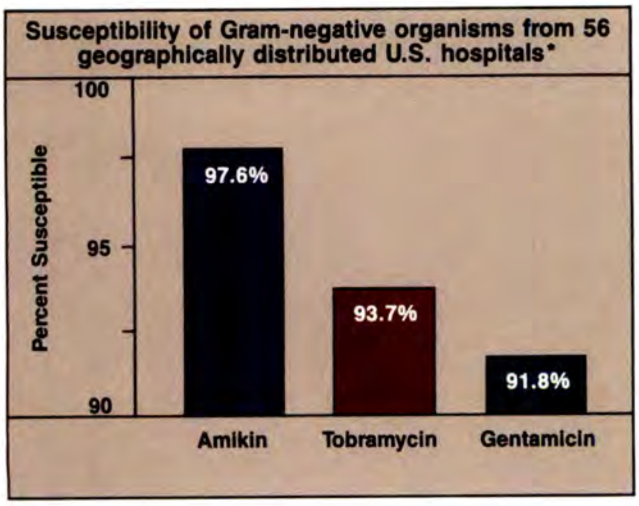
After the first dose, Amikin produces therapeutic blood levels that are more predictable than those of the other aminoglycosides.[1]



*Adapted from Holloway WJ: Management of sepsis in the elderly. *Am J Med* 80 (suppl 6B): 143-148, 1986.

First-Dose Antimicrobial Activity.

Amikin has the broadest spectrum of any aminoglycoside.[2]



Total Amikin isolates = 247,503

*In vitro data may not be directly correlated to clinical effectiveness. Data on file, Bristol Laboratories.

First-Dose Synergy.

In combination with antipseudomonal penicillins and latest generation cephalosporins, Amikin is overall the most synergistic of the aminoglycosides.[3,4]

First-Dose Economy.

The least expensive aminoglycoside is not necessarily the one with the lowest acquisition cost. It's the one *not* requiring replacement with a more effective agent.[5]

AMIKIN®

AMIKACIN SULFATE

BRIEF SUMMARY OF PRESCRIBING INFORMATION (1) 10/83

For complete prescribing information, please consult product literature.

WARNINGS

Patients treated with aminoglycosides should be under close clinical observation because of the potential ototoxicity and nephrotoxicity associated with their use.

Ototoxicity, both auditory and vestibular, can occur in patients treated at higher doses or for periods longer than those recommended. The risk of amikacin-induced ototoxicity is greater in patients with renal damage. High frequency deafness usually occurs first and can be detected only by audiometric testing. Vertigo may occur and may be evidence of vestibular injury.

The ototoxicity potential of amikacin in infants is not known. Until more safety reports become available, amikacin should be used in infants only in those specific circumstances when susceptibility testing indicates that other aminoglycosides cannot be used or are otherwise contraindicated, and when the infant can be observed closely for evidence of toxicity.

Aminoglycosides are potentially nephrotoxic. Renal and eighth-nerve function should be closely monitored in patients with known or suspected renal impairment and also in those whose renal function is initially normal but who develop signs of renal dysfunction during therapy. Such impairment may be characterized by decreased creatinine clearance, the presence of cells or casts, oliguria, proteinuria, decreased urine specific gravity or evidence of increasing nitrogen retention (increasing BUN or creatinine).

Evidence of impairment in renal, vestibular or auditory function requires discontinuation of the drug or dosage adjustment.

Serum concentrations should be monitored when feasible, and prolonged peak concentrations above 35 mcg/ml should be avoided. Urine should be examined for increased excretion of protein, the presence of cells and casts, and decreased specific gravity.

Concurrent and/or sequential use of topically or systemically neurotoxic or nephrotoxic antibiotics, particularly kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin should be avoided.

AMIKIN should not be given concurrently with potent diuretics (ethacrynic acid, furosemide, meralluride sodium, sodium mercaptomerin or mannitol). Some diuretics themselves cause ototoxicity, and intravenously administered diuretics enhance aminoglycoside toxicity by altering antibiotic concentrations in serum and tissue.

CONTRAINDICATIONS

A history of hypersensitivity to amikacin is a contraindication for its use.

WARNINGS

See "Warning" box above.

PRECAUTIONS

AMIKIN is potentially nephrotoxic, ototoxic, and neurotoxic. The concurrent or serial use of other ototoxic or nephrotoxic agents should be avoided either systemically or topically because of the potential for additive effects. Such agents include antibacterial drugs such as kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin as well as certain diuretic agents such as ethacrynic acid or furosemide.

Ototoxicity — See "Warning" box.

Nephrotoxicity — Since AMIKIN is present in high concentrations in the renal excretory system, patients should be well hydrated to minimize chemical irritation of the renal tubules. Kidney function should be assessed by the usual methods prior to starting therapy and daily during the course of treatment.

If signs of renal irritation appear (casts, white or red cells or albumin), hydration should be increased. A reduction in dosage (see "Dosage and Administration") may be desirable if other evidence of renal dysfunction occurs such as decreased creatinine clearance, decreased urine specific gravity, increased BUN, creatinine or oliguria. If azotemia increases or if a progressive decrease in urinary output occurs, treatment should be stopped.

Note: When patients are well hydrated and kidney function is normal the risk of nephrotoxic reactions with amikacin is low if the dosage recommendations (see "Dosage and Administration") are not exceeded.

Neurotoxicity — Neuromuscular blockade and muscular paralysis have been demonstrated in the cat with high doses of amikacin (188 mg/Kg). The possibility of neuromuscular blockade and respiratory paralysis should be considered when amikacin is administered concomitantly with anesthetic or neuromuscular blocking drugs. If blockade occurs, calcium salts may reverse this phenomenon.

Other — Cross-allergenicity among aminoglycosides has been demonstrated. As with other antibiotics the use of amikacin may result in overgrowth of nonsusceptible organisms. If this occurs, appropriate therapy should be instituted.

Pregnancy — Reproduction studies have been performed in rats and mice and have revealed no evidence of impaired fertility or harm to the fetus due to amikacin. There are no well-controlled studies in pregnant women but investigational experience does not include any positive evidence of adverse effects on the fetus. Although there is no clearly defined risk, such experience cannot exclude the possibility of infrequent or subtle damage to the fetus. AMIKIN should be used in pregnant women only when clearly needed.

It is not known whether this drug is excreted in human milk. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

ADVERSE REACTIONS

Ototoxicity — See "Warning" box.

Nephrotoxicity — Albuminuria, presence of red and white cells, casts, azotemia and oliguria have been reported.

Other — In addition to those described above, other adverse reactions which have been reported on rare occasions are skin rash, drug fever, headache, paresthesia, tremor, nausea and vomiting, eosinophilia, arthralgia, anemia, hypotension.

Overdosage — In the event of overdosage or toxic reaction, peritoneal dialysis or hemodialysis will aid in the removal of amikacin from the blood.

BRISTOL LABORATORIES

Bristol-Myers U.S. Pharmaceutical and Nutritional Group

"I'D LIKE TO MAKE AN APPOINTMENT WITH THE DOCTOR"

Be prepared, Doctor. More patients will be asking about colorectal cancer. According to a survey* conducted by the American Cancer Society, many people would like to receive more information about colorectal cancer, and 83% said they would want to be checked for it. Further, they are learning that this cancer can be detected *before* symptoms appear. The present cure rate is 44%. The cure rate *could* be as high as 75%, with early detection and appropriate management.

For asymptomatic persons the Society recommends annual digital rectal examination at age 40 and over; at age 50 and over, an annual stool blood test, as well as sigmoidoscopy every three to five years, following two initial annual negative sigmoidoscopies.

We're here to help. You can reach us at your local American Cancer Society office or write to our Professional Education Department at National Headquarters, 90 Park Avenue, New York, N.Y. 10016. Ask about the Society's Colorectal Check program of professional and public education for the early detection of colorectal cancer.

THROMBOSTAT™ (THROMBIN, USP), a trusted hemostatic aid, is now available in a pump spray form—permitting flexible and easy application. With the new THROMBOSTAT pump, you can achieve hemostasis in seconds over large body surface areas. Each depression of the pump offers an even distribution

SPRAY ON HEMOSTASIS

of THROMBOSTAT solution—allowing uniform hemostasis of the total area. The THROMBOSTAT pump is available in a convenient sterile kit that features a 20,000-unit vial of THROMBOSTAT (a practical size for procedures involving capillary bleeding), an appropriate measure of diluent, and a pump sprayer cap. The kit offers sterile packaging—permitting the entire contents to be brought directly into the sterile field. With the new THROMBOSTAT kit, it has never been simpler to control capillary bleeding.

Please see next page for brief summary of prescribing information.

THROMBOSTAT™ (THROMBIN, USP) (Bovine Origin)

Before prescribing, please see full prescribing information. A Brief Summary follows:

Thrombostat must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE: Thrombostat (Thrombin, USP) is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery solutions of Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS: Thrombostat is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING: Because of its action in the clotting mechanism, Thrombostat must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Thrombostat is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS: General: Consult the absorbable gelatin sponge product labeling for complete information for use prior to utilizing the thrombin-saturated-sponge procedure.

Pregnancy—Teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical (Bovine). It is also not known whether Thrombin, Topical (Bovine) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical (Bovine) should be given to a pregnant woman only if clearly indicated.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: An allergic type reaction following the use of Thrombostat for treatment of epistaxis has been reported. Febrile reactions have also been observed following the use of Thrombostat in certain surgical procedures but no cause-effect relationship has been established.

DOSAGE AND ADMINISTRATION: General: Solutions of Thrombostat may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc, solutions containing approximately 100 units per ml are frequently used. For this, 10 ml of diluent added to the 1000 unit package is suitable. Where bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1000 to 2000 units per ml may be required. For this the 5000 unit vial dissolved in 5 ml or 2.5 ml respectively, of the diluent supplied in the package is convenient. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate volume of diluent. In many situations, it may be advantageous to use Thrombostat (Thrombin, USP) in dry form on oozing surfaces.

Caution: Solutions should be used the day they are prepared. The solution may be used for up to 6 hours when stored at room temperature; up to 24 hours when stored under refrigeration, and, if necessary, up to 48 hours when stored frozen.

The following techniques are suggested for the topical application of Thrombostat.

1. The recipient surface should be sponged (not wiped) free of blood before Thrombostat is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the Thrombostat mixes freely with the blood as soon as it reaches the surface.
3. In instances where Thrombostat in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried Thrombostat is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place.

Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP as follows:

1. Prepare Thrombostat solution of the desired strength.
2. Immerse sponge strips of the desired size in the Thrombostat solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

Thrombostat Kit: Thrombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. The Kit may be used as follows:

1. Remove the Tyvek blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared and the pump sprayer cap inserted and seated on the Thrombostat solution vial. Note: Several strokes of the pump sprayer will be required before the Thrombostat solution is expelled.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument. **4173G014**

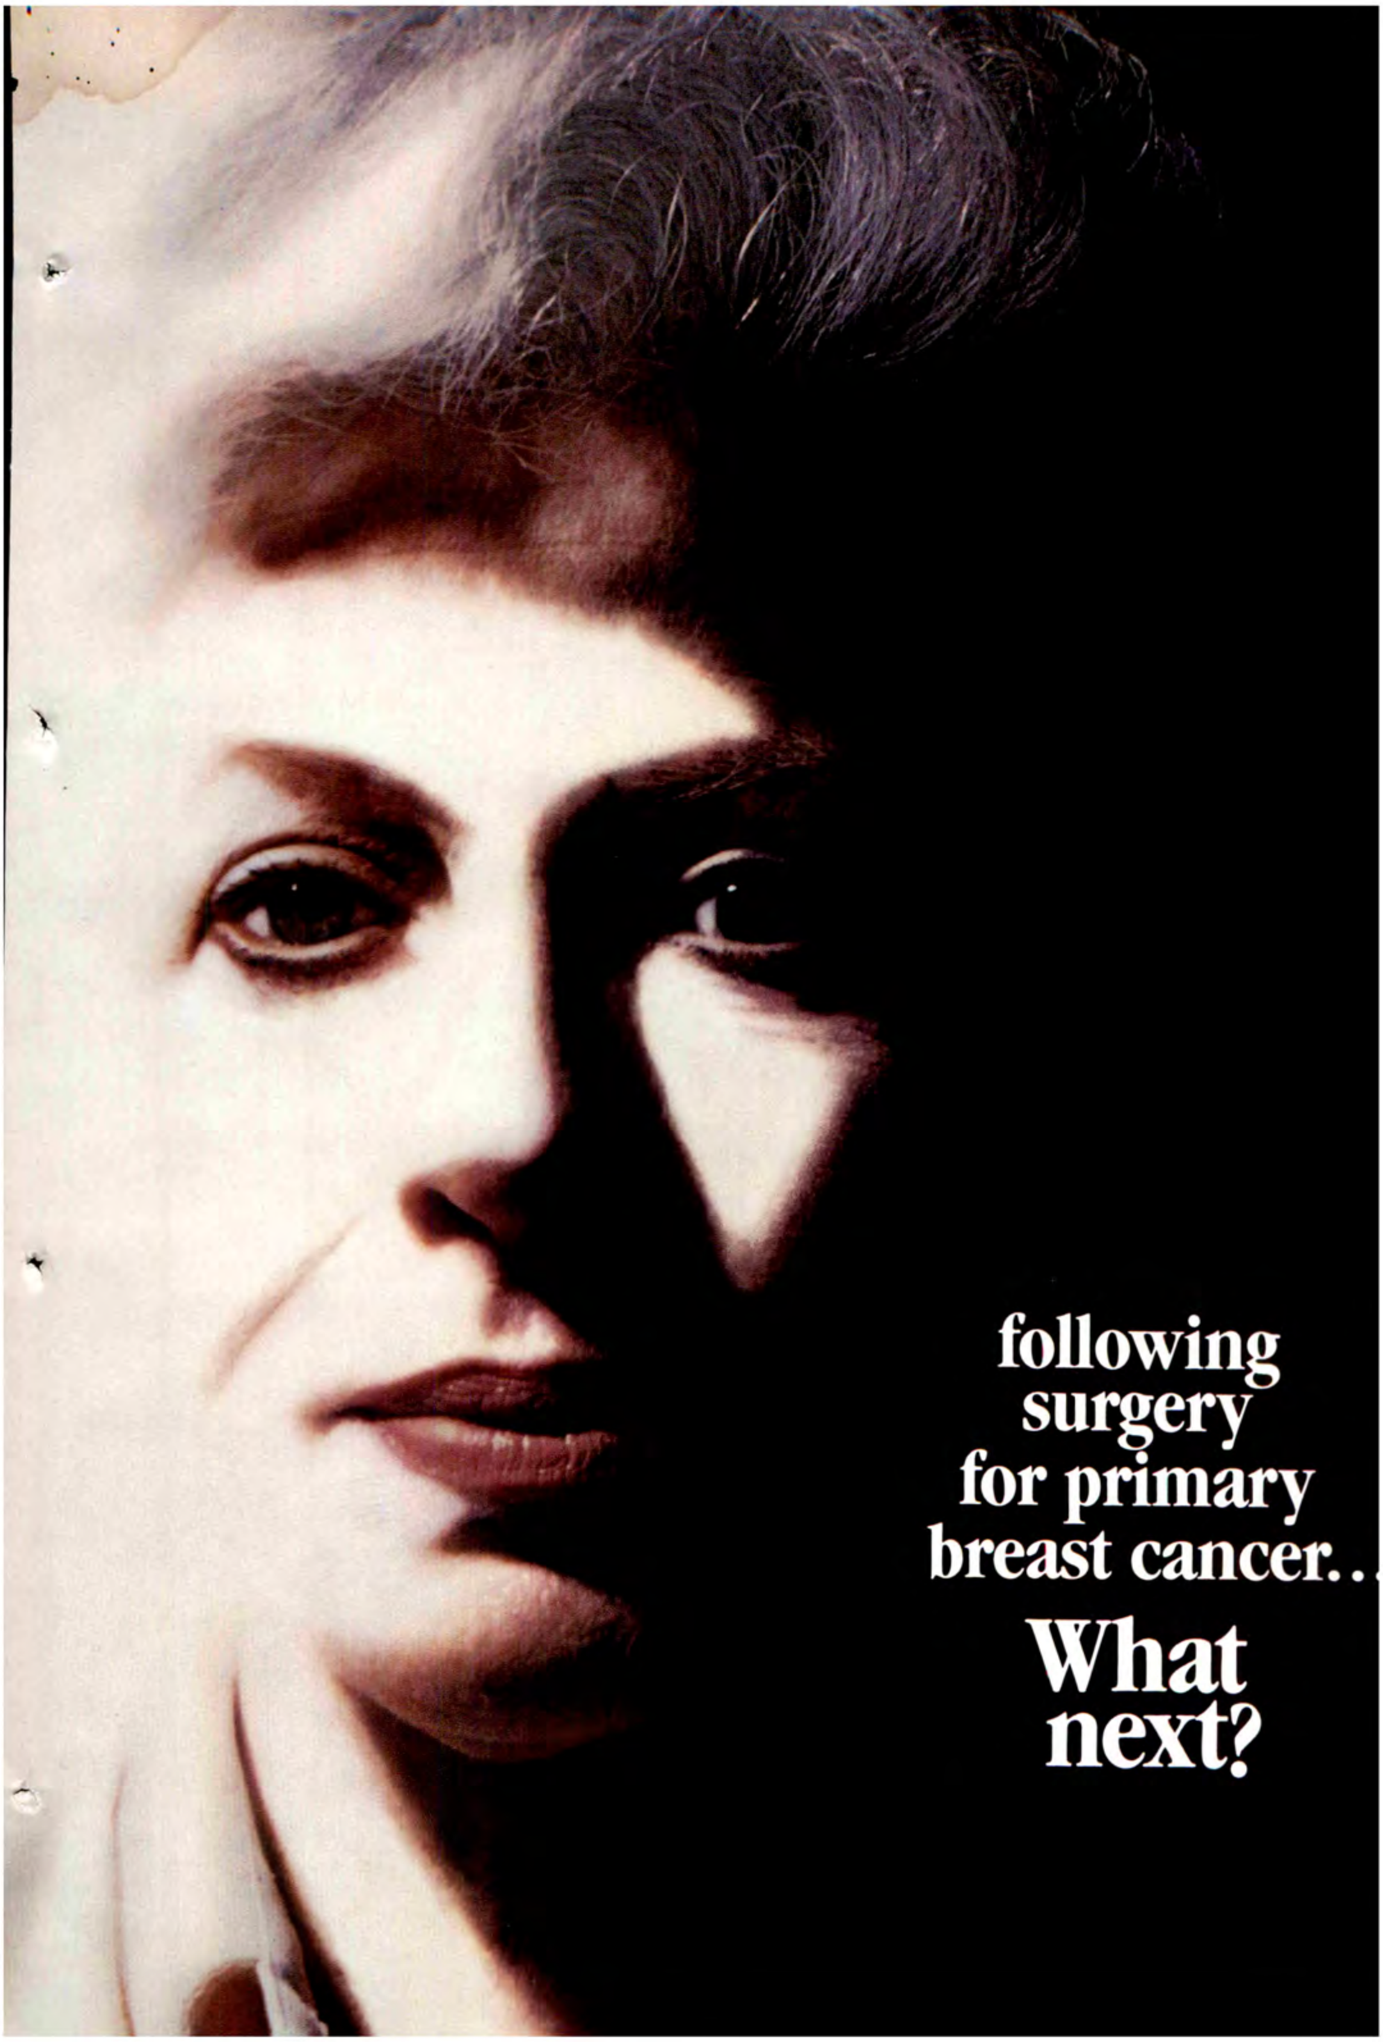
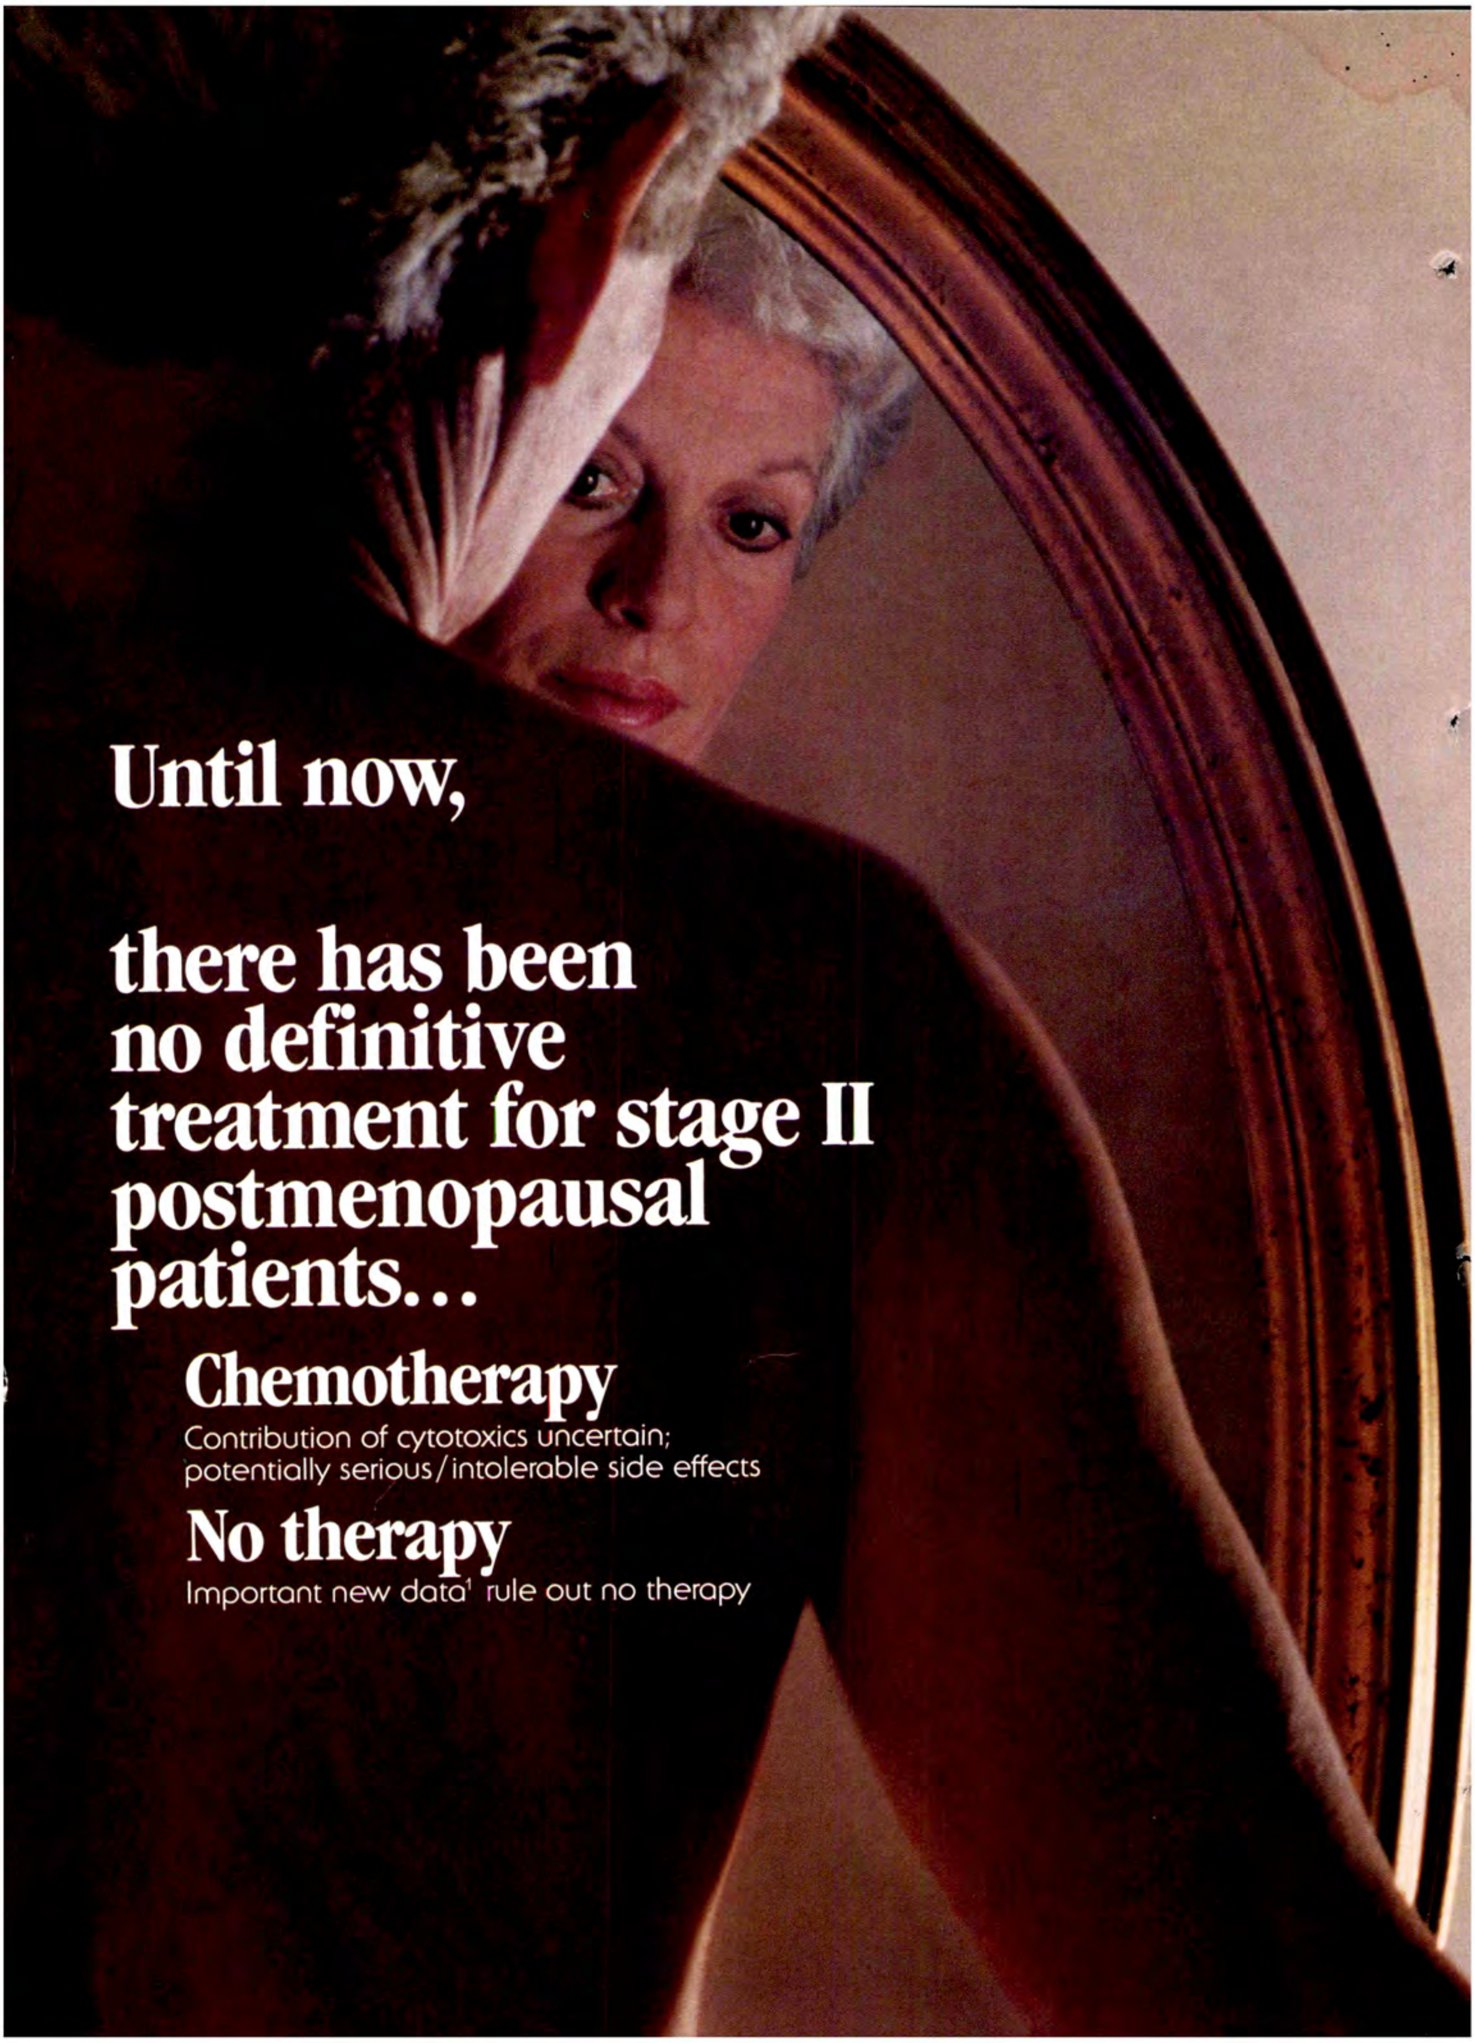
Help us keep win



following surgery for primary breast cancer...
What next?



Until now,
there has been no definitive treatment for stage II postmenopausal patients...
Chemotherapy
Contribution of cytotoxics uncertain; potentially serious/intolerable side effects
No therapy
Important new data[1] rule out no therapy

Today there is.

10 MG TABLETS

Nolvadex®

TAMOXIFEN CITRATE

Adjuvant Monotherapy

Now, the treatment of choice

A recent National Institutes of Health consensus report states that following surgery, "Tamoxifen [NOLVADEX] should now be regarded as standard therapy for postmenopausal patients with positive axillary lymph nodes and positive hormone receptor status."[1]

NOLVADEX increases disease-free time[2-5] by delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T_{1-3}, N_1, M_0). Moreover, NOLVADEX improves overall survival, with a 34% reduction in risk of mortality, as observed in the NOLVADEX Adjuvant Trial Organization (NATO) study.[4] This treatment is extremely well tolerated by patients[2-5]; in fact, one double-blind, placebo-controlled study demonstrated a NOLVADEX side effects profile similar to placebo.[2] And, since NOLVADEX has a mild side effects profile and is easy to administer, patients are afforded a better quality of life. NOLVADEX—today's promising breast cancer therapy for the postmenopausal woman—in the adjuvant setting and in metastatic disease.

Please see next page for brief summary of prescribing information.

STUART PHARMACEUTICALS
Division of ICI Americas Inc
Wilmington, Delaware 19897

10 MG TABLETS

Nolvadex®

TAMOXIFEN CITRATE

BRIEF SUMMARY

INDICATIONS AND USAGE: NOLVADEX is effective in the treatment of metastatic breast cancer in postmenopausal women. Available evidence indicates that patients whose tumors are estrogen receptor positive are more likely to benefit from NOLVADEX therapy.

NOLVADEX is effective in delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T1-3, N1, M0). The estrogen and progesterone receptor values may help to predict whether NOLVADEX therapy is likely to be beneficial. In some NOLVADEX adjuvant studies, most of the benefit to date has been in the subgroup with 4 or more positive axillary nodes.

CONTRAINDICATIONS: None known.

WARNINGS: Pregnancy Category D: NOLVADEX may cause fetal harm when administered to a pregnant woman. Individuals should not become pregnant while taking NOLVADEX. Effects on reproductive functions are expected from the antiestrogenic properties of the drug. In reproductive studies in rats at dose levels equal to or below the human dose, nonteratogenic developmental skeletal changes were seen and were found to be reversible. In addition, in fertility studies in rats and in teratology studies in rabbits using doses at or below those used in humans, a lower incidence of embryo implantation and a higher incidence of fetal death or retarded in utero growth were observed, with slower learning behavior in some rat pups. The impairment of learning behavior did not achieve statistical significance in one study, and, in another study where significance was reported, this was by comparing dosed animals with controls of another study. Several pregnant marmosets were dosed during organogenesis or in the last half of pregnancy. No deformations were seen and although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. There are no adequate and well-controlled studies in pregnant women. There have been reports of spontaneous abortions, birth defects, fetal deaths, and vaginal bleeding. If this drug is used during pregnancy or the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Ocular changes have been reported in a few patients who, as part of a clinical trial, were treated for periods greater than one year with NOLVADEX at doses at least four times the highest recommended daily dose of 40 mg. The ocular changes consist of retinopathy and, in some patients, there are also corneal changes and a decrease in visual acuity.

In addition, a few cases of ocular changes including visual disturbance, corneal changes, and/or retinopathy have been reported in patients treated with NOLVADEX at recommended doses. It is uncertain if these effects are due to NOLVADEX.

As with other additive hormonal therapy (estrogens and androgens), hypercalcemia has been reported in some breast cancer patients with bone metastases within a few weeks of starting treatment with NOLVADEX. If hypercalcemia does occur, appropriate measures should be taken and, if severe, NOLVADEX should be discontinued.

PRECAUTIONS: General: NOLVADEX should be used cautiously in patients with existing leukopenia or thrombocytopenia. Observations of leukopenia and thrombocytopenia occasionally have been made, but it is uncertain if these effects are due to NOLVADEX therapy. Transient decreases in platelet counts, usually to 50,000-100,000/cu mm, infrequently lower, have been occasionally reported in patients taking NOLVADEX for breast cancer. No hemorrhagic tendency has been recorded and the platelet counts returned to normal levels even though treatment with NOLVADEX continued.

Laboratory Tests: Periodic complete blood counts, including platelet counts, may be appropriate.

Carcinogenesis: While no conventional bioassay has been conducted, endocrine changes in immature and mature mice were investigated in a 13-month study. Granulosa cell ovarian tumors and interstitial cell testicular tumors were found in mice receiving NOLVADEX, but not in the controls.

Mutagenesis: No genotoxic potential has been found in a battery of in vivo and in vitro tests with pro- and eukaryotic test systems with drug metabolizing systems present.

Impairment of Fertility: Fertility in female rats was decreased following administration of 0.04 mg/kg for 2 weeks prior to mating through day 7 of pregnancy. There was a decreased number of implantations, and all fetuses were found dead.

Following administration to rats of 0.16 mg/kg from days 7-17 of pregnancy, there were increased numbers of fetal deaths. Administration of 0.125 mg/kg to rabbits during days 6-18 of pregnancy resulted in abortion or premature delivery. Fetal deaths occurred at higher doses. There were no teratogenic changes in either rat or rabbit segment II studies. Several pregnant marmosets were dosed with 10 mg/kg/day either during organogenesis or in the last half of pregnancy. No deformations were seen, and, although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. Rats given 0.16 mg/kg from day 17 of pregnancy to 1 day before weaning demonstrated increased numbers of dead pups at parturition. It was reported that some rat pups showed slower learning behavior, but this did not achieve statistical significance in one study, and in another study where significance was reported, this was by comparing dosed animals with controls of another study.

The recommended daily human dose of 20-40 mg corresponds to 0.4-0.8 mg/kg for an average 50 kg woman.

Pregnancy Category D: See WARNINGS.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from NOLVADEX, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

ADVERSE REACTIONS: The most frequent adverse reactions to NOLVADEX are hot flashes, nausea and vomiting. These may occur in up to one-fourth of patients, but are rarely severe enough to require discontinuation of treatment.

Less frequently reported adverse reactions are vaginal bleeding, vaginal discharge, menstrual irregularities and skin rash. Usually these have not been of sufficient severity to require dosage reduction or discontinuation of treatment.

Increased bone and tumor pain and, also, local disease flare have occurred, which are sometimes associated with a good tumor response. Patients with increased bone pain may require additional analgesics. Patients with soft tissue disease may have sudden increases in the size of preexisting lesions, sometimes associated with marked erythema within and surrounding the lesions and/or the development of new lesions. When they occur, the bone pain or disease flare are seen shortly after starting NOLVADEX and generally subside rapidly.

Other adverse reactions which are seen infrequently are hypercalcemia, peripheral edema, distaste for food, pruritus vulvae, depression, dizziness, light-headedness and headache. There have been infrequent reports of thromboembolic events occurring during NOLVADEX therapy. Since for cancer patients in general an increased incidence of thromboembolic events is known to occur, a causal relationship to NOLVADEX remains conjectural. An increased incidence has been reported when cytotoxins are combined with NOLVADEX.

If adverse reactions are severe, it is sometimes possible to control them by a simple reduction of dosage without loss of control of the disease.

OVERDOSAGE: Acute overdosage in humans has not been reported. Signs observed at the highest doses following studies to determine LD_{50} in animals were respiratory difficulties and convulsions. No specific treatment for overdosage is known; treatment must be symptomatic.

DOSAGE AND ADMINISTRATION: One or two 10 mg tablets twice a day (morning and evening). In the three single agent adjuvant NOLVADEX studies noted above (See Clinical Pharmacology), NOLVADEX was administered for two years. The optimal duration of adjuvant therapy is not known.

HOW SUPPLIED: Tablets containing tamoxifen as the citrate in an amount equivalent to 10 mg of tamoxifen (round, biconvex, uncoated, white tablet identified with NOLVADEX 600 debossed on one side and a cameo debossed on the other side) are supplied in bottles of 60 tablets and 250 tablets. Protect from heat and light.

WE HAVE ONLY GOOD THINGS TO SAY ABOUT CANCER OF THE COLON.

If detected early, the cure rate for colorectal cancer is very high. It can be as high as 75%.

Because we now know how to detect it early. And we know how to fight it once we detect it.

There are three simple checkup guidelines for men and women without symptoms.

One, get a digital exam every year. This is recommended for everyone over 40.

Two, get a stool blood test every year if you are over 50.

Three, after two initial negative tests one year apart, get a procto exam every three to five years if you are over 50.

These guidelines are the best protection against colorectal cancer you can have.

If you're not over 50, please give this information to friends and loved ones who are.

In any case, please help spread the word.

Good news doesn't always travel fast.

SUBCUTANEOUS
CLEFT LIP

Techniques in CLEFT LIP, NOSE AND PALATE RECONSTRUCTION

...show you the art of reconstructive plastic surgery for children born with cleft deformities

By Donald I. Kapetansky, M.D.

Foreword by D. Ralph Millard, Jr., M.D.

250 Beautiful, full-color illustrations...

. . . show you some of the most effective and efficient procedures in use today to correct cleft deformities in children. Sequential photographs of operations show each step of repair. Clear, close-up photographs show cleft deformities from various angles to help you fully understand the patient's condition. Detailed line drawings, full-color schematic diagrams, and explanatory text accompany the photographs and clarify important aspects of the deformities and the surgical techniques employed to correct them.

Complete coverage of surgical procedures

This book is divided into four parts, each focusing on a particular type of congenital deformity. Parts I and II focus, respectively, on primary and deferred corrective procedures for unilateral and bilateral cleft lip and nose reconstruction. These sections are primarily concerned with improving the child's appearance. Part III deals with cleft palate reconstruction and pharyngeal-flap procedures. This section details surgical techniques aimed at restoring the function of the palate in speech production—without producing iatrogenic facial deformities. Two types of transverse pharyngeal-flap surgery are described in this section. Part IV deals with some unusual cleft problems and three case studies in long-term cleft reconstruction.

Considers the total perioperative picture

With 25 years of practice and more than 2500 cleft operations to his credit, the author brings a wide range of experience and an authoritative viewpoint to this work. From a concentration on techniques that require fewer staged procedures, to methods of suturing the skin, to the use of long-acting local anesthetics even with general anesthesia—you'll find a multitude of suggestions for pre- and postoperative care and interoperative planning that aim to ease the strain on children enduring multiple surgical procedures.

Flexible and innovative therapies for the management of cancer patients

Management of Head and Neck Cancer:

A Multidisciplinary Approach

Edited by Rodney R. Million, M.D., and Nicholas J. Cassisi, M.D.
20 Contributors.

". . . a superb volume on head and neck cancer that will at once become the standard of reference . . . comprehensive, with 36 chapters ranging from the history of diagnosis and treatment of head and neck cancer . . . to such modern-day concerns as costs in management of these cancers. In style and format, in illustration and graphics, and particularly in the overall connectedness of the whole, the authors and publisher have produced a work sure to become a classic."—*The Journal of the American Medical Association* ***684 Pages. 941 Illustrations, including 43 in Full Color. 232 Tables. 1984. $99.50.***

OTOLARYNGOLOGY (Loose Leaf) 5-Volumes

with Annual Revision Service

Editor-in-Chief: Gerald M. English, M.D., F.A.C.S./ 220 Contributors.

4,900 Pages. 3,600 Illustrations, 214 Tables. $400.00 (includes first year new page service). Add $10 for 4th class postage and handling. 10% discount on purchase price when payment accompanies order.

...in severe post-op N&V

Compazine®

Injection 5 mg./ml.

brand of

prochlorperazine

Available in 25 mg. suppositories, too.

Do not use 'Compazine' in pediatric surgery.

©SmithKline Beckman Corporation, 1985

See brief summary of prescribing information on adjacent page.

The antiemetic physicians prescribe most*

COMPAZINE®
brand of
prochlorperazine

See complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: For control of severe nausea and vomiting.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; pediatric surgery; use in children under 2 years of age or under 20 lbs.; use in children for conditions for which dosage has not been established.

Warnings: The extrapyramidal symptoms which can occur secondary to 'Compazine' may be confused with the central nervous system signs of an undiagnosed primary disease responsible for the vomiting, e.g., Reye's syndrome or other encephalopathy. The use of 'Compazine' and other potential hepatotoxins should be avoided in children and adolescents whose signs and symptoms suggest Reye's syndrome.

May cause tardive dyskinesia in some patients on neuroleptic (antipsychotic) therapy, usually long-term. This syndrome consists of potentially irreversible, involuntary dyskinetic movements. The risk of tardive dyskinesia and likelihood of irreversibility are thought related to duration of treatment and total cumulative dose of neuroleptic drugs.

Use in patients with bone marrow depression only when potential benefits outweigh risks. Patients who develop a hypersensitivity reaction (e.g., blood dyscrasias or jaundice) to a phenothiazine generally should not be reexposed to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Prochlorperazine may intensify or prolong the action of other C.N.S. depressants.

Use in pregnancy is not recommended except in cases so serious and intractable that, in the physician's judgment, drug intervention is required and potential benefits outweigh possible hazards. There have been instances of prolonged jaundice, extrapyramidal signs, hyperreflexia or hyporeflexia in newborn infants whose mothers received phenothiazines. There is evidence that phenothiazines are excreted in the breast milk of nursing mothers.

Precautions: The antiemetic action of 'Compazine' may mask the signs and symptoms of overdosage of other drugs and may obscure the diagnosis and treatment of other conditions such as intestinal obstruction, brain tumor and Reye's syndrome (See Warnings). Postoperative aspiration of vomitus has occurred in a few surgical patients who received prochlorperazine as an antiemetic. When used concomitantly with cancer chemotherapeutic drugs, may obscure vomiting as a sign of these agents' toxicity. Deep sleep and coma have been reported with prochlorperazine, usually with overdosage.

Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent *in vitro*, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis.

Permanently stop neuroleptic therapy if neuromuscular reactions occur in pregnant women or in children.

In children with acute illnesses or dehydration, use only under close supervision. Avoid high doses and parenteral administration when cardiovascular system is impaired since hypotension has occurred. Use cautiously in patients with glaucoma. Use with caution in persons who will be exposed to extreme heat since phenothiazines may interfere with thermoregulatory mechanisms. Phenothiazines can diminish the effect of oral anticoagulants. Phenothiazines can produce alpha-adrenergic blockade. Thiazide diuretics may accentuate orthostatic hypotension that may occur with phenothiazines. Antihypertensive effects of guanethidine and related compounds may be counteracted when phenothiazines are used concomitantly. Concomitant administration of phenothiazines with propranolol results in increased plasma levels of both drugs and may also precipitate phenytoin toxicity. Phenothiazines may lower the convulsive threshold; dosage adjustments of anticonvulsants may be necessary. Presence of phenothiazines may produce false positive phenylketonuria (PKU) test results. Patients should not receive 'Compazine' 48 hours before or 24 hours after myelography with the contrast medium metrizamide.

Adverse Reactions: Drowsiness, dizziness, amenorrhea, blurred vision, skin reactions. Hypotension. Cholestatic jaundice, leukopenia, agranulocytosis. Fatty changes in the liver have been observed in a few patients who died while receiving the drug (no causal relationship has been established). Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, tardive dyskinesia, and a variant, tardive dystonia. Contact dermatitis is a possibility if 'Compazine' Injection (solution) inadvertently gets on hands or clothing.

Other adverse reactions reported with 'Compazine' or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., severe hypotension in mitral insufficiency or pheochromocytoma). Grand mal and petit mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat and organophosphorus insecticides; dryness of mouth, nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, ejaculatory disorders/impotence, priapism, atonic colon, urinary retention, miosis and mydriasis; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; pancytopenia, thrombocytopenic purpura, eosinophilia, hemolytic anemia, aplastic anemia; biliary stasis; hyperglycemia, hypoglycemia, glycosuria, lactation, galactorrhea, gynecomastia, menstrual irregularities, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema; angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; mild fever after large I.M. doses; increased appetite; increased weight; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; neuroleptic malignant syndrome, which may be fatal; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits.

EKG changes have been reported. Discontinue long-term, high-dose therapy gradually.

Note: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported.

Supplied: Tablets—5, 10 and 25 mg., in bottles of 100; Spansule® capsules—10, 15 and 30 mg., in bottles of 50; Injection—5 mg./ml. in 2 ml. ampuls, 10 ml. vials and 2 ml. disposable syringes; Suppositories—2½, 5 and 25 mg.; Syrup—5 mg./5 ml.; Single Unit Packages of 100 (intended for institutional use only)—5 and 10 mg. tablets; 10, 15 and 30 mg. 'Spansule' capsules.

There is a road.

Many cancer patients need transportation to and from treatments. That's why the American Cancer Society has formed groups of volunteers across the United States who give a few hours of their time each month to drive them. The road to recovery can be a long and difficult one, but it can be that much easier when there are friends who can help along the way.

La Crosse, WI 54601

An Equal Opportunity Employer

NUBAIN® IM IV SC
nalbuphine HCl

Brief Summary of Prescribing Information

INDICATIONS For the relief of moderate to severe pain. NUBAIN can also be used for preoperative analgesia, as a supplement to surgical anesthesia, and for obstetrical analgesia during labor.

CONTRAINDICATIONS NUBAIN should not be administered to patients who are hypersensitive to it.

WARNINGS Drug Dependence NUBAIN has been shown to have a low abuse potential which is approximate to that of pentazocine. When compared with drugs which are not mixed agonist-antagonists, it has been reported that nalbuphine's potential for abuse would be less than that of codeine and propoxyphene. Psychological and physical dependence and tolerance may follow the abuse or misuse of nalbuphine. Therefore, caution should be observed in prescribing it for emotionally unstable patients, or for individuals with a history of narcotic abuse. Such patients should be closely supervised when long-term therapy is contemplated. Care should be taken to avoid increases in dosage or frequency of administration which in susceptible individuals might result in physical dependence. Abrupt discontinuation of NUBAIN following prolonged use has been followed by symptoms of narcotic withdrawal, i.e., abdominal cramps, nausea and vomiting, rhinorrhea, lacrimation, restlessness, anxiety, elevated temperature and piloerection. **Use in Ambulatory Patients** NUBAIN may impair the mental or physical abilities required for the performance of potentially dangerous tasks such as driving a car or operating machinery. Therefore, NUBAIN should be administered with caution to ambulatory patients who should be warned to avoid such hazards. **Use in Emergency Procedures** Maintain patient under observation until recovered from NUBAIN effects that would affect driving or other potentially dangerous tasks. **Use in Children** Clinical experience to support administration to patients under 18 years is not available at present. **Use in Pregnancy (other than labor)** Safe use of NUBAIN in pregnancy has not been established. Although animal reproductive studies have not revealed teratogenic or embryotoxic effects, nalbuphine should only be administered to pregnant women when, in the judgement of the physician, the potential benefits outweigh the possible hazards. **Use During Labor and Delivery** NUBAIN can produce respiratory depression in the neonate. It should be used with caution in women delivering premature infants. **Head Injury and Increased Intracranial Pressure** The possible respiratory depressant effects and the potential of potent analgesics to elevate cerebrospinal fluid pressure (resulting from vasodilation following CO_2 retention) may be markedly exaggerated in the presence of head injury, intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, potent analgesics can produce effects which may obscure the clinical course of patients with head injuries. Therefore, NUBAIN should be used in these circumstances only when essential, and then should be administered with extreme caution. **Interaction With Other Central Nervous System Depressants** Although NUBAIN possesses narcotic antagonist activity, there is evidence that in nondependent patients it will not antagonize a narcotic analgesic administered just before, concurrently, or just after an injection of NUBAIN. Therefore, patients receiving a narcotic analgesic, general anesthetics, phenothiazines, or other tranquilizers, sedatives, hypnotics, or other CNS depressants (including alcohol) concomitantly with NUBAIN may exhibit an additive effect. When such combined therapy is contemplated, the dose of one or both agents should be reduced. **Sulfites Sensitivity** NUBAIN contains sodium metabisulfite, a sulfite that may cause allergic-type reactions (e.g., hives, itching, wheezing, anaphylaxis) in certain susceptible persons. Although the overall prevalence of sulfite sensitivity in the general population is probably low, it is seen more frequently in asthmatics or in atopic nonasthmatic persons.

PRECAUTIONS Impaired Respiration At the usual adult dose of 10mg/70 kg, NUBAIN causes some respiratory depression approximately equal to that produced by equal doses of morphine. However, in contrast to morphine, respiratory depression is not appreciably increased with higher doses of NUBAIN. Respiratory depression induced by NUBAIN can be reversed by NARCAN® (naloxone hydrochloride) when indicated. NUBAIN should be administered with caution at low doses to patients with impaired respiration (e.g., from other medication, uremia, bronchial asthma, severe infection, cyanosis or respiratory obstructions). **Impaired Renal or Hepatic Function** Because NUBAIN is metabolized in the liver and excreted by the kidneys, patients with renal or liver dysfunction may overreact to customary doses. Therefore, in these individuals, NUBAIN should be used with caution and administered in reduced amounts. **Myocardial Infarction** As with all potent analgesics, NUBAIN should be used with caution in patients with myocardial infarction who have nausea or vomiting. **Biliary Tract Surgery** As with all narcotic analgesics, NUBAIN should be used with caution in patients about to undergo surgery of the biliary tract since it may cause spasm of the sphincter of Oddi.

ADVERSE REACTIONS The most frequent adverse reaction in 1066 patients treated with NUBAIN is sedation 381 (36%). Less frequent reactions are sweaty/clammy 99 (9%); nausea/vomiting 68 (6%); dizziness/vertigo 58 (5%); dry mouth 44 (4%); and headache 27 (3%). Other adverse reactions which may occur (reported incidence of 1% or less) are: **CNS Effects** Nervousness, depression, restlessness, crying, euphoria, floating, hostility, unusual dreams, confusion, faintness, hallucinations, dysphoria, feeling of heaviness, numbness, tingling, unreality. The incidence of psychotomimetic effects, such as unreality, depersonalization, delusions, dysphoria and hallucinations has been shown to be less than that which occurs with pentazocine. **Cardiovascular** Hypertension, hypotension, bradycardia, tachycardia. **Gastrointestinal** Cramps, dyspepsia, bitter taste. **Respiration** Depression, dyspnea, asthma. **Dermatological** Itching, burning, urticaria. **Miscellaneous** Speech difficulty, urinary urgency, blurred vision, flushing and warmth. **Patients Dependent on Narcotics** Patients who have been taking narcotics chronically may experience withdrawal symptoms upon the administration of NUBAIN. If unduly troublesome, narcotic withdrawal symptoms can be controlled by the slow intravenous administration of small increments of morphine, until relief occurs. If the previous analgesic was morphine, meperidine, codeine, or other narcotic with similar duration of activity, one-fourth of the anticipated dose of NUBAIN can be administered initially and the patient observed for signs of withdrawal, i.e., abdominal cramps, nausea and vomiting, lacrimation, rhinorrhea, anxiety, restlessness, elevation of temperature or piloerection. If untoward symptoms do not occur, progressively larger doses may be tried at appropriate intervals until the desired level of analgesia is obtained with NUBAIN. **Management of Overdosage** The immediate intravenous administration of NARCAN® (naloxone hydrochloride) is a specific antidote. Oxygen, intravenous fluids, vasopressors and other supportive measures should be used as indicated. The administration of single doses of 72 mg of NUBAIN subcutaneously to eight normal subjects has been reported to have resulted primarily in symptoms of sleepiness and mild dysphoria.

NUBAIN® delivers pain-stopping power comparable to morphine/meperidine, and "balances potent analgesia with strong antagonist effects... resulting in fewer adverse responses."[1]

- ☐ Documented "ceiling" on respiratory depression. "A unique safety factor among potent analgesics."[2]
- ☐ Fast onset of action
- ☐ Long-lasting pain relief
- ☐ Low incidence of nausea and vomiting
- ☐ Nonconstipating
- ☐ No significant hemodynamic changes
- ☐ Low abuse potential—nonscheduled

Now available in 20 mg/ml ampul, vial, and syringe.
Also available in 10 mg/ml ampul and vial.

Endoscopy in Colonic Volvulus

THOMAS E. BROTHERS, M.D., WILLIAM E. STRODEL, M.D., F.A.C.S., and FREDERIC E. ECKHAUSER, M.D., F.A.C.S.

From the Department of Surgery, University of Michigan, Ann Arbor, Michigan

Flexible fiberoptic gastrointestinal endoscopy has greatly simplified the diagnosis and treatment of colonic volvulus. The management of 39 patients with colonic volvulus treated over 9 years was reviewed. Five per cent were treated with rectal tube decompression alone, 23% were treated with either sigmoidoscopic or colonoscopic reduction, and 26% were treated exclusively with operation. Endoscopic reduction was attempted in nearly half of the patients in preparation for operation. Recurrent volvulus occurred in 57% of patients initially treated with endoscopic reduction alone. Sigmoidoscopic examination did not confirm the diagnosis in 24% of instances in which it was used, although colonoscopy was always diagnostic. The overall mortality rate was 8%, but increased to 25% in patients with gangrene of the colon. Three patients who later proved to have gangrene of the colon had a normal initial sigmoidoscopic examination. Two of these patients died of intra-abdominal sepsis from a perforated colon. In five patients an accurate endoscopic diagnosis of gangrene prompted immediate exploration. None of these patients died. Endoscopy is a safe and effective diagnostic tool for the initial evaluation of patients with suspected colon volvulus. In addition, endoscopy may result in therapeutic decompression and may provide visual assessment of the viability of the bowel mucosa, thus assisting in the timing of appropriate operative treatment.

VOLVULUS OF THE COLON is a surgical emergency that can lead to significant morbidity and mortality if unrecognized or inadequately treated. Torsion of the bowel on its mesentery occurs most commonly in patients with an excessively mobile colon and may compromise the blood supply to the colon.[1] Factors that may predispose to excessive motility include an elongated mesentery or a mesentery with a narrow base. The most important prognostic factor for the patient with volvulus is the viability of the colon at operation.[2-4]

The management of colonic volvulus depends in part on the site of the volvulus. Successful treatment relies on early recognition and timely intervention. Historically, volvulus has been managed by either transanal rectal tube decompression or by operative intervention. The latter may consist of simple detorsion, tube decompression (cecostomy), fixation of the mobile bowel to the abdominal wall (cecopexy), or resection with primary or delayed anastomosis.[5,6]

The role of endoscopy in the diagnosis and treatment of volvulus has evolved gradually. Operative exploration, as described by Moynihan in the first part of the twentieth century, was considered mandatory when volvulus was proven or even suspected.[7] In 1947, Bruusgaard described rigid sigmoidoscopy as part of the nonoperative management of sigmoid volvulus.[8] When coupled with the placement of a rectal tube, sigmoidos-

Submitted for publication: December 17, 1986.

copy resulted in a low mortality rate (2–3%), but a high rate of recurrence (40–60%).[9] The development of flexible fiberoptic endoscopy has facilitated decompression of the dilated and friable bowel.[10–12] When used before a definitive operation, the patient's condition can be stabilized, allowing preparation of the bowel for any definitive procedure, including resection and primary anastomosis. In addition, total colonoscopy permits evacuation of bowel contents proximal to the site of the volvulus, and in rare cases has been used to reduce a cecal volvulus. In some institutions colonic endoscopy is used alone as definitive treatment for colon volvulus. This review examines a 9-year experience with endoscopic intervention in colonic volvulus at the University of Michigan.

Methods

The medical records of 39 patients with colonic volvulus treated at the University of Michigan Affiliated Hospitals from October 1, 1975 to October 1, 1984 were reviewed. Patients were categorized according to age and sex, presenting signs and symptoms, and associated medical disorders. The anatomic site of volvulus was identified as full cecal, cecal bascule (cecal fold), transverse colon, splenic flexure, or sigmoid colon. The diagnosis of colonic volvulus was determined by the following modalities, exclusively or in combination: abdominal x-ray, barium enema, history and physical examination, sigmoidoscopy, colonoscopy, operation, or autopsy. Therapeutic procedures included rectal tube decompression, sigmoidoscopy, colonoscopy, laparotomy with either cecopexy, cecostomy, resection and primary anastomosis, or resection and enterostomy. The presence of gangrenous bowel was noted. Instances of recurrent volvulus or of original misdiagnosis were recorded. Patients who had endoscopic decompression followed by planned operation were not considered as having recurrent volvulus.

Results

Thirty-nine patients were identified over a 9-year period at two hospitals: 20 at a university referral center and 19 at a county hospital in a metropolitan area. The average patient age was 59 years. The mean ages for patients with sigmoid and cecal volvulus were 65 years and 50 years, respectively. Fifty-seven per cent of patients were men. Forty-one per cent of patients had had previous abdominal operations, and 13% had had previous episodes of colonic volvulus. Neurologic or psychiatric disorders were present in 36% of patients, and 36% were residents of nursing homes, psychiatric hospitals, or state institutions. Twenty-eight per cent of patients regularly used laxatives.

The most common presenting signs and symptoms were abdominal distention (95%), abdominal pain and cramping (92%), and nausea and vomiting (54%). Less common findings included leukocytosis (white blood count > 10,000/mm^3 in 50%, obstipation (49%), recent constipation (49%), fever (38%), absent bowel sounds (33%), and diarrhea (28%). Only 15% of patients were hemodynamically unstable.

Diagnostic modalities used included plain abdominal x-rays (90%), laparotomy (69%), sigmoidoscopy (54%), barium enema (28%), and colonoscopy (21%). Although not always diagnostic of volvulus, results of all of the above studies except sigmoidoscopy were abnormal. Twenty-four per cent of sigmoidoscopic examinations (18% of all endoscopic procedures) were normal despite the presence of volvulus, yielding a sensitivity of 0.76. False-negative results usually occurred in cases where a more proximal volvulus was present. In no case was the diagnosis of volvulus made solely at autopsy.

The volvulus occurred in the sigmoid colon, cecum, and transverse colon in 56%, 41%, and 5% of patients, respectively. Cecal bascule was diagnosed in one patient (2%).

An average of 1.7 procedures were performed per patient (see Fig. 1). Rectal tube decompression with or without endoscopy was used in 33% of patients. Two patients treated exclusively with rectal tube decompression had no recurrences. Fifty-one per cent of patients had sigmoidoscopic examination, and 15% had a colonoscopic examination. Colonoscopy was successful in five of eight (63%) attempts at reduction of a sigmoid volvulus, and sigmoidoscopy succeeded in 11 of 21 (52%) attempts. In patients in whom endoscopy was the initial therapeutic modality, the recurrence rate was 57%. Laparotomy was performed in 89% of patients. Operations for sigmoid volvulus included resection and primary anastomosis (79%) and resection with colostomy (21%). Cecal volvulus was treated with cecostomy (31%), cecopexy (23%), resection with ileostomy (23%), resection and primary anastomosis (15%), and simple detorsion (8%). Both patients with transverse colon volvulus had colectomy with colostomy. Recurrence after resection and primary anastomosis occurred in one instance of sigmoid volvulus (3%) due to inadequate initial resection. Colon gangrene occurred in 23% of patients. Seventy-seven per cent of these patients were initially examined endoscopically. The overall mortality rate for colonic volvulus was 8%, but increased to 25% in patients with gangrenous changes of the colon. Three patients who later proved to have gangrene of the colon had a normal initial sigmoidoscopic examination. Two of these patients died of intra-abdominal sepsis from a perforated colon. Five patients with necrotic mucosa noted at the time of endoscopy had emergent resection without evidence of perforation. All of these patients survived.

Discussion

The successful treatment of colonic volvulus depends on early recognition of the nature and site of the condition. Although colonic volvulus is not the most common cause of intestinal obstruction (1–6%), it does occur more frequently in institutionalized individuals and in persons over 60 years old.[2,4,13,14] There is speculation that sigmoid volvulus is associated with chronic constipation and high-fiber diets. These factors may result in elongation of the colon and its mesentery, which predisposes it to torsion. In Iran and Russia, where the diet has a high fiber content, there is a high incidence of sigmoid volvulus.[2,8] Indeed, in these two countries, sigmoid volvulus accounts for nearly 50% of all cases of intestinal obstruction. Congenital abnormalities of the colon such as malrotation or inadequate fixation of the cecum have been implicated as the underlying cause of cecal volvulus in younger patients. The average patient age in the current series was 65 years for sigmoid volvulus and 50 years for cecal volvulus. The relative incidence of the various sites of volvulus found in our series is similar to previously published reports (Table 1). Nearly one third of the cases occurred in institutionalized patients, of whom at least 49% had constipation and 28% were chronically taking laxatives.

The presenting signs and symptoms of colon volvulus were the same as any condition that produces intestinal obstruction and include abdominal distention, colic, nausea, vomiting, and obstipation. Signs of systemic toxicity such as fever, leukocytosis, or shock were often absent, even in the presence of bowel gangrene, and were therefore not reliable diagnostic or prognostic indicators in this patient population.

Besides the history and physical examination, the diagnostic study most commonly used was abdominal roentgenography. Barium contrast studies were infrequently used to avoid the possibility of perforation and resultant barium peritonitis. Colonoscopic examination usually confirmed the diagnosis of volvulus. Bloody colonic contents or dark blue or black colonic mucosa were reliable signs of ischemia or impending necrosis. Sigmoidoscopy was frequently unremarkable in cases of colonic volvulus, particularly if the involved segment was proximal to the sigmoid colon. However, a normal colonoscopic examination of the entire colon eliminated the possibility of volvulus. In addition, total colonoscopy would have been useful to identify other causes of colon distention, such as nonobstructive colonic dilatation, or other mechanical factors such as polyps or cancers.[15]

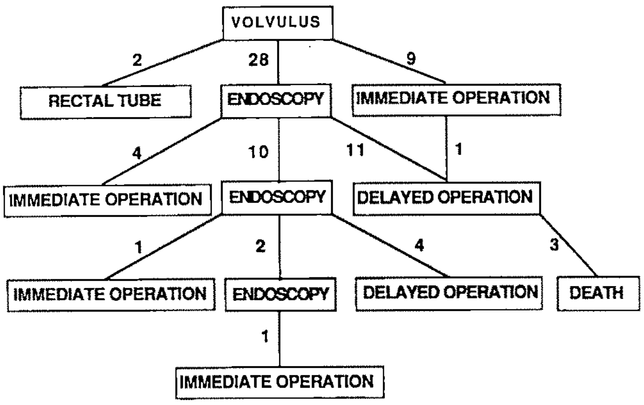

FIG. 1. Treatment progression in 39 patients with colonic volvulus.

Successful colonoscopic reduction of cecal volvulus has been reported sporadically,[12] but was not helpful in our series in either of two attempts. In addition to a high failure rate, attempts at colonoscopic reduction of cecal volvulus may only delay necessary operative intervention and probably should not be considered.

The presence of colonic gangrene as an important prognostic factor has often been demonstrated. In a review of the literature, Ballantyne found that the overall mortality rate of colonic volvulus was 10.6%, but increased to 80% when the colon was necrotic.[16] Reviewing the American experience, the outcome was much more favorable, although the mortality rate was still higher for necrotic than for viable colon (26% *vs.* 11%, respectively).[2] O'Mara et al. reported a 33% mortality rate when gangrenous changes were present compared with an overall mortality rate of 12% when the colon was viable.[6] The overall mortality may also depend on the location of the volvulus. Mortality rates range from 7 to 40% for sigmoid volvulus, 0 to 17% for cecal volvulus, 0 to 75% for transverse colon volvulus, and 0 to 7% for splenic flexure volvulus.[2-6,8,9,14,17] The type of operation may affect the outcome at each particular site, although this has not been proven consistently. Five of our patients had gangrenous colon identified at the initial endoscopic examination. Immediate laparotomy and resection of the necrotic colon were performed with

TABLE 1. *Incidence of Colonic Volvulus by Site*

Type	Current Series (1986), N = 39	Ballantyne et al.[2] (1985), N = 137	Jain and Seth[4] (1968), N = 102
Sigmoid	56%	43%	71%
Full cecal	41%	47%	29%
Transverse	5%	3%	0%
Cecal bascale	2%	5%	—
Splenic flexure	0%	2%	—

no deaths. Two patients who subsequently proved to have gangrene of the colon had unremarkable initial sigmoidoscopic examinations and later died. Perforation with intra-abdominal sepsis developed in both patients before death, possibly resulting from the delay in treatment. A third patient survived despite a similar error.

The dangers of endoscopic examination in cases of suspected colon volvulus include missing a (usually more proximal) segment of necrotic bowel and delaying timely resection of the necrotic segment. Perforation of a compromised segment of bowel may also occur. Such examinations must be performed by experienced endoscopists using minimal air insufflation and manipulation to minimize this possibility.

Flexible colonoscopy is useful as a temporizing measure to allow elective preparation of the patient and the colon, but it should be followed initially by definitive operative intervention. Endoscopic decompression alone, although successful in most patients, is followed by a high recurrence rate. The presence of bloody colonic contents, evidence of strangulation and ischemia, or the presence of signs of peritoneal irritation should indicate the need for termination of the procedure and immediate preparation of the patient for operation. An unremarkable sigmoidoscopic examination does not eliminate the possibility of a more proximal colon volvulus. However, a normal colonscopic examination of the entire colon does eliminate the diagnosis of colon volvulus and suggests the need to search for other causes for colon distention, such as nonobstructive colonic dilatation.

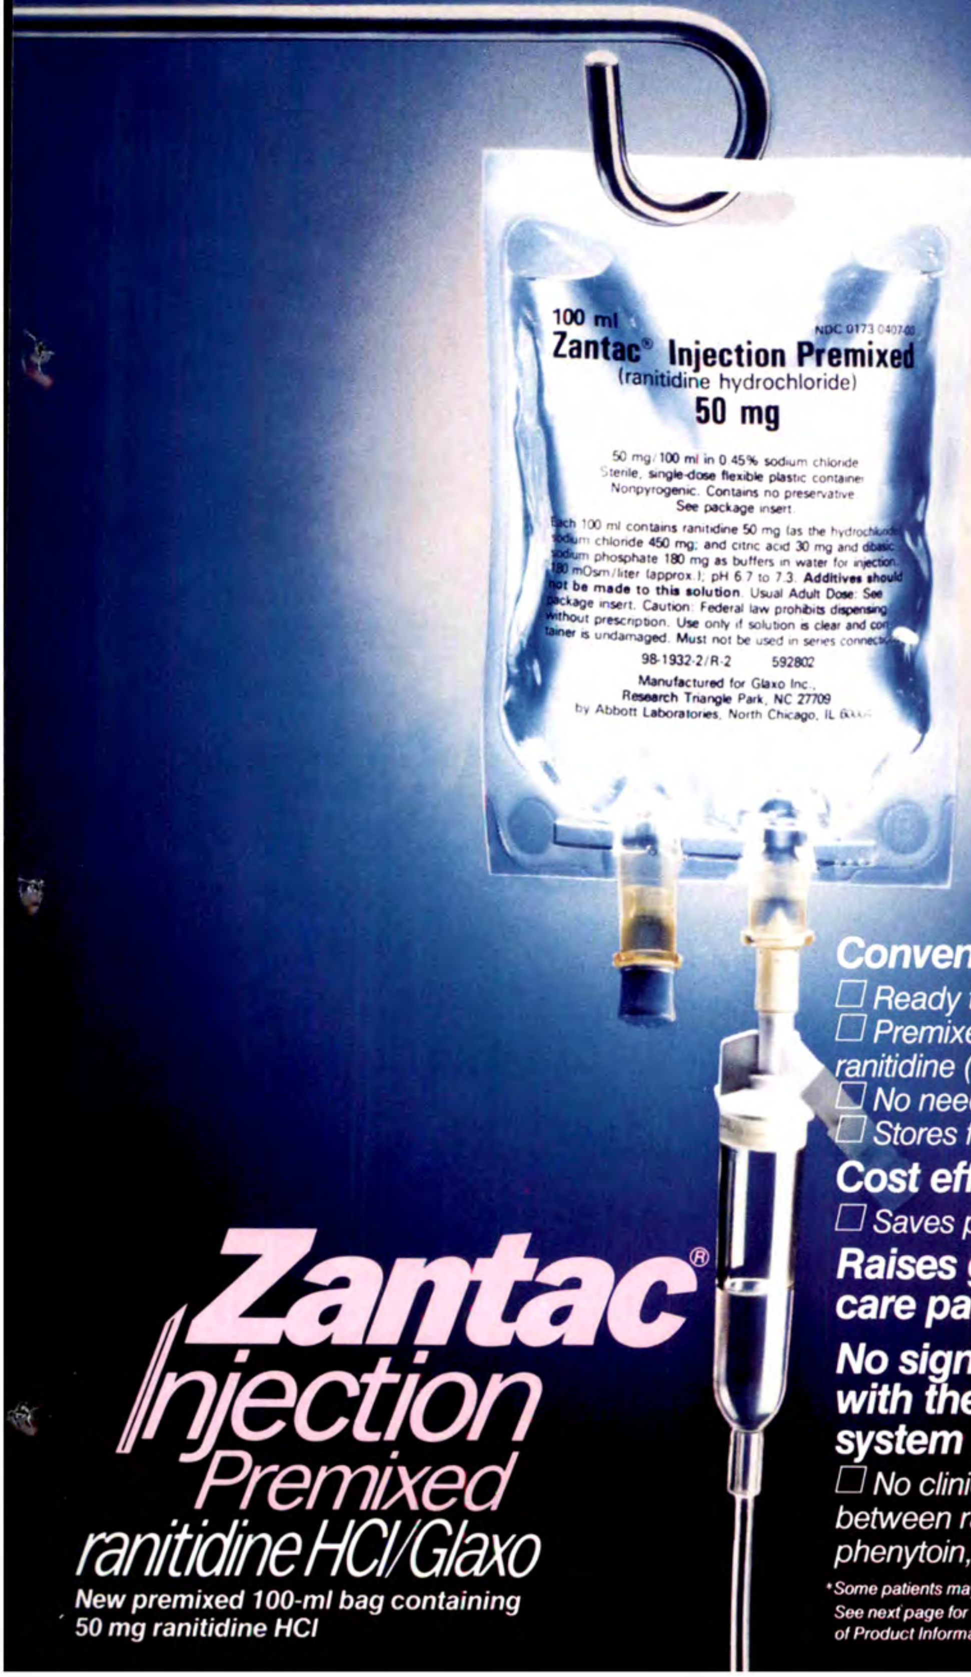
INTRODUCING
THE NEW LOOK
IN ACID SUPPRESSION



100 ml
NDC 0173 0407-00
Zantac® Injection Premixed
(ranitidine hydrochloride)
50 mg
50 mg/100 ml in 0.45% sodium chloride
Sterile, single-dose flexible plastic container
Nonpyrogenic. Contains no preservative
See package insert.
Each 100 ml contains ranitidine 50 mg (as the hydrochloride) sodium chloride 450 mg; and citric acid 30 mg and dibasic sodium phosphate 180 mg as buffers in water for injection. 180 mOsm/liter (approx.); pH 6.7 to 7.3. Additives should not be made to this solution. Usual Adult Dose: See package insert. Caution: Federal law prohibits dispensing without prescription. Use only if solution is clear and container is undamaged. Must not be used in series connection
98-1932-2/R-2 592802
Manufactured for Glaxo Inc.,
Research Triangle Park, NC 27709
by Abbott Laboratories, North Chicago, IL

Convenient

☐ Ready to use–no mixing needed
☐ Premixed 100-ml bag, containing 50 mg ranitidine (as the hydrochloride)
☐ No need to refrigerate
☐ Stores for up to 18 months

Cost effective

☐ Saves pharmacy and nursing time

Raises gastric pH acid in critical care patients for up to 8 hours*

No significant drug interactions with the hepatic P-450 enzyme system at recommended doses

☐ No clinically significant drug interactions between ranitidine and theophylline, phenytoin, or warfarin

Zantac®
Injection
Premixed
ranitidine HCl/Glaxo

New premixed 100-ml bag containing 50 mg ranitidine HCl

*Some patients may require q6h dosing.
See next page for brief summary of Product Information.

ZANTAC® Injection
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC® Headache, sometimes severe, seems to be related to ZANTAC administration. Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain have been reported. There have been rare reports of malaise, dizziness, somnolence, insomnia, vertigo, tachycardia, bradycardia, premature ventricular beats, and arthralgias. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.

Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.

Although controlled studies have shown no antiandrogenic activity, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Incidents of rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia, have been reported, as well as rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
(NDC 0173-0362-38) 2-ml single-dose vials (Tray of 10)
(NDC 0173-0363-39) 10-ml multidose vials (Singles)
(NDC 0173-0362-01) 2-ml single-dose, prefilled, disposable cartridge-needle units (Tray of 10)
(NDC 0173-0362-00) 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

The Role of the Small Intestine in Ammonia Production after Gastric Blood Administration

STEPHEN P. SUGARBAKER, M.D.,* ARTHUR REVHAUG, M.D., and DOUGLAS W. WILMORE, M.D.

From the Department of Surgery, Harvard Medical School, Brigham and Women's Hospital, Boston, Massachusetts

It is commonly believed that the digestion of intraluminal blood by colonic bacteria is the primary cause of increased ammonia production after upper gastrointestinal hemorrage. To evaluate the role of the small intestine in ammonia production, blood, amino acids, or water (5 mL/kg) was administered as a meal or enema to awake dogs with chronic indwelling catheters. After blood meals, intestinal ammonia production increased rapidly to peak at 60 minutes and returned to basal levels. This response was mimicked by the gastric administration of ammoniagenic amino acids. No change in ammonia production occurred with water administration. In contrast, colonic blood administration resulted in a gradual rise in ammonia production, and peaked at 150 minutes. Amino acid enemas resulted in a similar but somewhat more rapid response. No change occurred with water enemas. After gut decontamination, ammonia production did not increase after blood enemas. However, the rapid increase in ammonia production persisted after blood meals. It is concluded that both the small bowel and colon participate in the augmented ammonia production that occurs after upper gastrointestinal hemorrhage. Gut decontamination reduces ammonia production by altering the colonic microflora, but is not specific therapy directed towards amino acid metabolism by the enterocytes of the small bowel and thus, does not alter the ammonia produced by the small intestine.

After upper gastrointestinal tract hemorrhage, ammonia concentration in the portal venous blood is elevated.[1,2] The primary site of the increased ammonia production has been believed to be the colon, where bacteria deaminate intraluminal nitrogenous substances. The ammonia produced diffuses into the portal blood stream.[2-5] Other studies have questioned the role of intraluminal bacteria as the primary sources of ammonia generation. For example, Nance et al. administered blood meals to germ-free Eck-fistula dogs and found that the ammonia concentrations in the peripheral blood rose to levels comparable to those observed in animals colonized with bacteria.[6] Rudman and associates administered ammoniagenic amino acids to patients with portosystemic shunting. They observed a rise in ammonia concentration in peripheral blood after intravenous amino acid infusion and concluded that the usual mechanisms of amino acid metabolism were responsible for the augmented ammonia generation.[7]

Other studies have demonstrated that the enterocytes of the small bowel extract glutamine and use this amino acid as a primary oxidizable fuel.[8,9] The ammonia produced is released into the portal blood stream. Estimates suggested that glutamine degradation by the small intestine accounts for approximately half of the ammonia produced by the gastrointestinal tract in the basal state.[10]

The current studies evaluated the role of the small bowel in intestinal ammonia production after a blood meal. These investigations demonstrate that both the small intestine and colon participate in the ammoniageneis that occurs after gastrointestinal bleeding. However, different mechanisms appear to be involved in the processing of intraluminal blood protein.

Materials and Methods

Preparation of Catheterized Dogs

Nineteen conditioned male and female mongrel dogs weighing between 13 and 35 kg (mean: 25 kg) were studied. An average of three studies were performed with each animal. The animals were maintained in accordance with the recommendations of the Committee on

Animal Care of the Harvard Medical School and Guidelines for the Care and Use of Laboratory Animals (DHSS Publication No. 85-23, Revised 1985). The dogs were acquired from an animal research supplier after they had undergone screening and treatment for parasites. The female dogs were nongravid. All dogs were obtained at least 3 days before operation to allow acclimatization to our facility.

All animals had laparotomy, splenectomy, and placement of chronically indwelling aortic, portal venous, and mesenteric infusion catheters as previously described.[11] After insertion of the catheters into the vessels, the distal ends were exteriorized through a puncture wound in the right flank and needles fitted with injection ports were attached to the catheter tips. The injection ports were placed subcutaneously on the right upper flank of the animal. This allowed chronic access to the blood stream after transcutaneous needle puncture of the injection ports.

The animals were housed individually after operation and received a daily food ration (50 g/kg) of Agway Respond 2000 (Agway, Syracuse, NY) (approximate calorie distribution: no less than 21% protein and 19% fat, with the remaining energy as carbohydrate) between 12:00 A.M. and 4:00 P.M. All animals maintained their preoperative weight or gained weight during a recovery period of at least 1 week. Animals entered into the study met the following criteria: (1) recovered 8 or more days after laparotomy, (2) rectal temperature <39 C, (3) no evidence of infection on physical examination, (4) hematocrit >30%, (5) consumption of all daily food ration with normal stools, (6) normal behavior and energy level, and (7) ability to stand quietly in a Pavlov stand.

Study Design

On the day before the study, the food pan was removed at 4:00 P.M. All studies were performed between 7:00 A.M. and 2:00 P.M. in animals fasted more than 15 hours. On the morning of the study, the dogs were exercised and then placed in a Pavlov stand. Rectal temperature was taken, and the catheter injection ports entered by percutaneous puncture with 21-gauge needles. All catheters were flushed with heparinized saline (2 units of heparin/mL 0.9% saline).

Infusion of a solution of para-aminohippurate sodium (PAH, Merck, Sharp, and Dome, West Point, PA) in 0.9% saline (0.5 g PAH/100 mL 0.9% saline) was begun *via* the mesenteric infusion catheter. After an initial priming dose, the solution was infused at a rate of 0.70 mL/min *via* a Harvard pump (Harvard Equipment Co., South Natick, MA). After at least 45 minutes of infusion, steady-state dye concentrations were achieved and basal blood samples were obtained.[12] Six basal sample pairs were drawn simultaneously from the aortic and portal venous catheters for determination of whole blood ammonia, glutamine, glutamate, and PAH. The first three pairs were drawn at 5-minute intervals, and after 10 minutes, the second three pairs were drawn in a similar manner.

The animals then received either a meal or enema composed of one of the following: blood, an amino acid solution, or water. All meals or enemas were administered in a volume of 5 mL/kg. Meals were administered *via* an orogastric tube inserted through a wooden bite block with a hole in its center, which was placed in the dog's mouth. The tube and bite block were removed immediately after meal administration. Enemas were administered slowly *via* a Foley catheter that was advanced maximally (35 cm) into the animal's descending colon. After enema administration the tube was clamped and the catheter was pulled back until the Foley balloon was just proximal to the anal sphincter. The Foley balloon was then inflated with 20 mL of tap water and allowed to rest in the rectal vault for the remainder of the study period. The rectal tube was well tolerated by the animals, and its presence facilitated retention of the enemas.

Samples for whole blood ammonia and PAH were drawn simultaneously and in triplicate from the aortic and portal venous catheters at 30, 60, 90, 150, and 210 minutes after meal or enema administration. Triplicate samples for whole blood glutamine and glutamate were similarly drawn at 30, 90, and 210 minutes. At each time point three sample pairs were drawn: one pair was drawn 5 minutes before the time, the second was drawn at the specific time, and the third pair was drawn 5 minutes after the time point. Glutamine and glutamate determinations were not performed after the administration of the amino acid solutions.

Blood aliquots for ammonia, glutamine, and glutamate were immediately deproteinized with 10% perchloric acid placed in ice, periodically centrifuged, and filtered. The filtrates were pH adjusted and stored at −20 C until analysis by an enzymatic assay.[13] PAH samples were deproteinized with 10% trichloroacetic acid, filtered, and stored at −20 C until measurement by a spectrophotometric technique.[14] Whole blood ammonia determinations were performed using a spectrophotometric enzymatic assay (Sigma Chemical Co., St. Louis, MO).

Preparation of Blood and Amino Acid Meals and Enemas

Blood for meals or enemas was harvested from a donor dog less than 24 hours before each study. The average quantity harvested was approximately 200 mL. Blood was withdrawn, heparinized (1000 units), and refrigerated until 1 hour before the study. During this time the blood was warmed in room temperature until administered. Aliquots from each donor sample were taken for analysis of whole blood nitrogen[15] and ammonia concentration.

The amino acid solutions were prepared from the following four ammoniagenic amino acids[7]: glutamine (gln), serine (ser), threonine (thr) (Sigma Chemical Co., St. Louis, MO), and glycine (gly) (Fisher Scientific, Fair Lawn, NJ). The amino acids were weighed to provide a final concentration of gln 0.028 M, ser 0.12 M, thr 0.091 M, and gly 0.19 M, which approximated their concentrations in whole blood as free amino acids and as constituents of blood proteins.[16] The amino acids were mixed in tap water and administered within 10 minutes to minimize hydrolysis. A sample of each solution was taken for ammonia determination before administration. Tap water alone was also given by meal or enema and served as a control study. All meals or enemas were followed by a 50-mL tap water flush.

Gut Decontamination and Quantitative Stool Cultures

Six chronically catheterized dogs had gut decontamination as previously described.[17] At least 7 days after catheter insertion, antibiotic therapy was initiated. Animals received neomycin sulfate, 50 mg/kg, cephalothin sodium, 50 mg/kg, natamycin, 8 mg/kg, and polymyxin B, 10 mg/kg, twice daily for 7–8 days. The antibiotics were mixed in 100 mL of tap water and administered *via* an orogastric tube. The animals received their last dose of antibiotics the afternoon before the study and were fasted overnight. Each animal was studied twice and received a blood meal and a blood enema on the 5th or 7th–8th day of antibiotic treatment. The order in which the studies were performed (blood meal or enema) was sequentially alternated. The studies were performed after the previously described protocol.

Quantitative stool cultures were performed on each animal before the initiation of antibiotic therapy and after gut decontamination on the morning of blood meal and enema administration. Stool was harvested from the rectal vault using sterile technique and placed in a sterile container. A weighed sample (0.5 g) was suspended in 5 mL of sterile 0.9% saline and thoroughly homogenized. Seven serial dilutions were prepared ranging from 0.1 to 0.6×10^{-11} g stool/mL. One-milliliter aliquots of each dilution were plated in quadruplicate on blood agar plates (Gibco Laboratories, Lawrence, MA). All plates were incubated at 35 C for 48 hours. Two plates from each dilution were incubated in room air, and the other two were placed in a Gaspack Anaerobic jar (Microbiology Systems, Cockeysville, MD). After 48 hours, the plates were inspected for growth. Only the plates with discreet colonies were counted. The counts of duplicate plates were averaged to determine the number of colony-forming units per milliliter of aliquot plated. This number was then corrected by the dilution factor to calculate the number of colony-forming units per gram of stool. For each study, the final number of aerobes and anaerobes represents the average of all the dilutions where colonies could be counted (usually 2–3 plates).

Calculations

Portal blood flow was calculated using the dye dilution technique as previously described[12] and expressed per kilogram of body weight. For each study and substrate, the basal value for the arterial and portal venous concentration, portal venous–arterial (PV-A) concentration difference, and portal blood flow was calculated as the mean of the six basal measurements. Substrate exchange for each point in time was calculated as the mean of the product of portal blood flow and PV-A concentration difference; the six basal exchange rates were averaged for each substance to calculate basal substrate exchange, whereas the triplicate exchange rates were averaged for the specific time point after a meal or an enema. The values at each point in time from all studies within a treatment group were meaned.

For each individual experiment, the basal–peak response for each parameter was calculated by subtraction of the basal from the maximal value after a meal or enema. The time of peak response was determined by inspection of each individual response curve. Total ammonia production was calculated by integrating the area above basal subtended by each ammonia production curve. For each treatment group, these calculations were averaged to determine the mean basal–peak response, average time of peak response, and mean total ammonia production.

Statistical Analysis

The data were tested for distribution and found to be normally distributed; parametric methods were used to make all comparisons. Basal PV-A concentration differences were t-tested to determine if they were different than zero. Correlation was used to compare the arterial and portal concentrations of each substrate in the basal state. Within a treatment group, substrate concentrations, PV-A concentration differences, portal blood flow, and substrate exchange at each time point were compared with basal values (T = 0) using Dunnett's test in a blocked manner.[18] Regression analysis was used to determine the relationship between a specific measurement and time. Basal-to-peak response, time of peak response, and total ammonia production were com-

TABLE 1. *Average Values for Substrate Concentration, Blood Flow, and Gastrointestinal Exchange Measured in the Basal State (Mean ± SEM)**

(−) designates uptake, (+) designates release.

pared between groups by unpaired t-test. Paired t-test was used to compare blood meals and blood enemas after gut decontamination as the same studies were done in each animal.

Dunnett's test was performed on a Hewlett Packard 9845 microcomputer (Hewlett Packard, Palo Alto, CA) using the statistical software package Analyzer (1985 version by Dr. B. J. Ransil, Department of Medicine, Beth Israel Hospital, Boston, MA). All other calculations were performed using the Harvard School of Public Health computer (Boston, MA) using the Minitab statistical software package (Ed Magnin, 1983, Pennsylvania State University, University Park, PA). All data are expressed as mean ± SEM.

Results

Basal Studies

The overnight preparation of the animals was the same in 52 studies performed in 17 animals; these data form the basis for the basal measurements (Table 1). The mean portal ammonia concentration was 349 ± 13 μmol/L, almost twice the concentration found in arterial blood. Both of these levels were similar to previous reports from this laboratory[8] and elsewhere.[6] Basal portal glutamine concentration was 676 ± 16 μmol/L, approximately 10% lower than the mean arterial concentration and similar to previous reports.[11] In contrast, portal glutamate levels were approximately 10% higher than arterial levels. All the PV-A concentration differences were significantly different from zero, indicating that the gastrointestinal tract extracted or released the substances measured.

Mean basal portal blood flow measured in 33 studies was 28 ± 2 mL/min/kg, similar to values previously reported in splenectomized animals.[11] Gastrointestinal exchange of ammonia, glutamine, and glutamate were similar to rates previously reported.[8] In studies in which flow was not measured, the average basal portal blood flow was used to calculate substrate exchange in these animals. When both measured and derived exchange rates were averaged, the combined results for the 52 studies were similar to the rates measured in the 33 studies (Table 1).

In all studies, arterial and portal concentration were generally related; the correlation (r^2) between arterial and portal venous ammonia concentrations was 0.44, for arterial and portal glutamine levels was 0.92, and for arterial and portal glutamate concentrations was 0.85 ($p < 0.05$ for all relationships). There was, however, no significant relationship between the arterial and portal venous concentrations of these substances and their respective rates of gastrointestinal exchange, suggesting that other factors participate in the maintenance of these blood levels.

Effect of Blood and Water Meals

The effect of blood administered by orogastric tube on intestinal substrate flux was studied in eight animals. After blood administration, there was a prompt rise in portal venous ammonia, glutamine, and glutamate concentrations (Tables 2 and 3). These levels remained elevated for up to 90 minutes, then returned to normal basal concentrations. During this time there was a slight but significant increase in the arterial concentrations of glutamine and glutamate. The increases in portal concentration were reflected by significant widening of the PV-A gradient for ammonia and a narrowing of the gradient for glutamine. Portal blood flow remained constant after blood meals. Gastrointestinal production of ammonia increased significantly between 30 and 90 minutes compared with basal release rates. Glutamine extraction decreased significantly at 30 minutes, whereas glutamate production increased significantly at 90 minutes.

The effect of water meals was studied in seven animals. After administration of water in volumes equal to that of blood, there was no significant change in concentrations of ammonia, glutamine, or glutamate in the

* $p < 0.01$ when compared with T = 0 by Dunnett's test.

portal vein (Tables 2 and 3). However, arterial glutamine concentration rose gradually with time ($r^2 = 0.89$, $p < 0.05$), to a level significantly greater than the initial basal concentration. No significant alteration of arterial ammonia or glutamate concentration occurred. The PV-A gradient for each substrate remained constant as did portal blood flow; hence exchange rates for each substrate were constant throughout the study period.

When the basal-to-peak concentration differences after blood and water meals were compared, the rises in the portal concentration of ammonia, glutamine, and glutamate were significantly different from the water meal (Table 4). Similarly, the basal-to-peak response for ammonia production was greater after blood administration, as was the total quantity of ammonia produced (Table 4, Fig. 1).

Effect of Blood and Water Enemas

The effect of blood administered by rectal catheter was studied in eight animals. After colonic blood administration, there was a gradual rise with time in portal ammonia ($r^2 = 0.93$, $p < 0.01$), ammonia PV-A difference ($r^2 = 0.98$, $p < 0.001$), and in intestinal ammonia production ($r^2 = 0.74$, $p < 0.05$, Fig. 2). These levels were significantly greater than initial basal values at 150

and 210 minutes (Table 5). No significant change was observed in arterial ammonia concentration. Portal blood flow remained constant throughout the study period. No significant changes occurred in the portal concentrations of glutamine or glutamate, nor in their respective PV-A concentration differences or rates of gastrointestinal exchange (Table 6).

The effect of a water enema was studied in eight animals. When water was administered in volumes equal to that of blood, no significant changes occurred (Tables 5 and 6). Sham enemas were performed in five additional animals. This involved rectal catheterization without volume administration; no significant changes from basal occurred in the substrate concentrations after this manipulation (data not shown).

Comparison of Route of Blood Administration

Basal-to-peak responses between blood meals and enemas were compared to determine the effect of the route of blood administration (Table 7). Responses for portal ammonia, PV-A concentration difference, and intestinal ammonia production were similar. However, for all these measurements, the time of peak response was significantly delayed after colonic blood administration. The peak responses for blood meals occurred at 60 ± 30 minutes, compared with the peak response time of 150 ± 30 minutes after blood enemas. Total ammonia production was similar in each group. The average quantity of ammonia present in the blood administered as meals and enemas was 1.57 μmol/kg, and the ammonia produced was 99% greater than this quantity. The average quantity of whole blood nitrogen administered in the blood meals and enemas was 11 mmol/kg, and only 3.6% of the total nitrogen administered was recovered as ammonia after meal or enema administration.

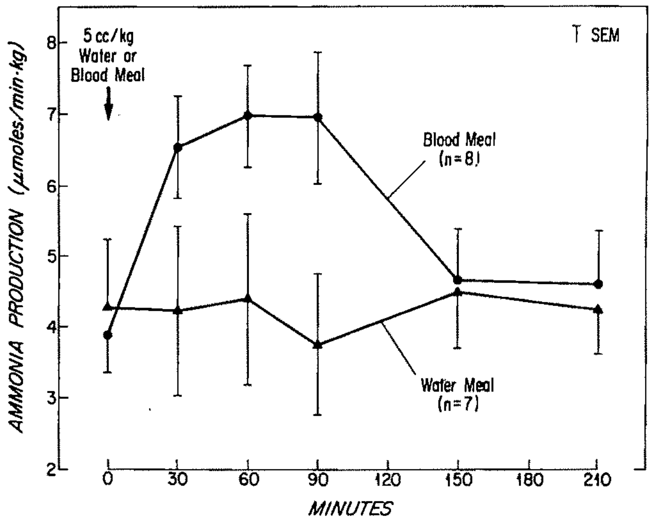

FIG. 1. After gastric intubation and blood administration, gastrointestinal ammonia production greatly increased between 30 and 90 minutes, then returned to basal levels. Ammonia production did not change after water administration.

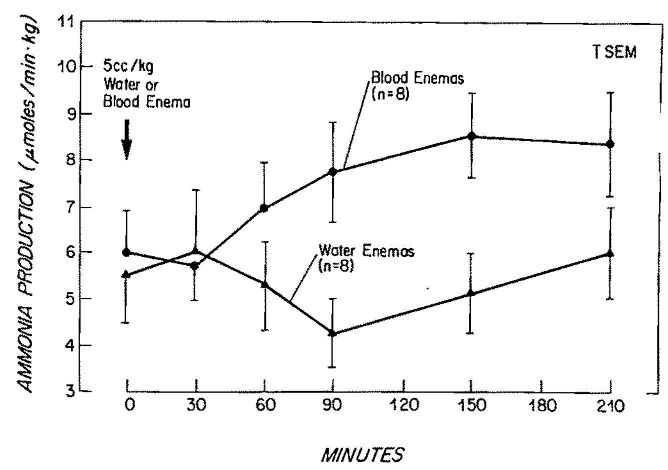

FIG. 2. After instillation of blood into the colon, ammonia production rose gradually and was still elevated by 210 minutes. Ammonia production did not change after water enemas.

The mean peak response for arterial ammonia was significantly greater after meals than after enemas. No difference in the time of peak response of arterial ammonia was observed.

Effect of Amino Acid Meals and Enemas

To evaluate the effect of digested protein on ammonia produced by the gastrointestinal tract, amino acids were administered by meal or enema. After amino acid meals, a rapid, significant rise occurred in the arterial and portal concentrations of ammonia at 30 minutes, with both concentrations returning to basal values by 60 minutes (Table 8). Portal blood flow remained constant after amino acid meals. Gastrointestinal ammonia production increased significantly at 30 minutes and returned to basal value by 60 minutes.

The effect of the same amino acid solution adminis-

tered by a rectal catheter on the intestinal flux of ammonia was studied in eight animals. After the administration of amino acid enemas in volumes equal to those of meals, portal ammonia concentration increased significantly by 60 minutes and remained elevated over basal concentrations for the remainder of the study period (Table 8). This elevation in portal ammonia concentration was reflected by significant widening of the PV-A concentration gradient over the basal value during the same time period. A transient but significant elevation in arterial ammonia occurred at 90 minutes. Portal blood flow remained constant after amino acid enemas. Gastrointestinal ammonia production increased significantly from 60 to 150 minutes compared with basal release rates.

The basal-to-peak responses for portal and arterial ammonia concentration as well as intestinal ammonia production were similar in the animals given amino acid meals or enemas (Table 9). However, the basal-to-peak ammonia PV-A concentration difference was significantly greater after colonic instillation of amino acids compared with gastric administration. For all responses, the time of peak response over basal was significantly delayed after enemas compared with after meals. Although amino acid enemas tended to produce more total ammonia for the study period compared with

meals, no significant difference between the integrated areas was detected.

The average quantity of ammonia administered in the amino acid meals and enemas was ≤0.59 μmol/kg, and in each case accounted for ≤6.0% of the total ammonia produced. The average nitrogen dose administered in the amino acid solution was 2.2 mmol/kg. For amino acid meals, 9.4 ± 2.9% of this quantity was recovered as ammonia nitrogen. For enemas, 20 ± 5.0% of the nitrogen was recovered as ammonia.

Effects of Gut Decontamination on Ammonia Production

Initial stool cultures demonstrated a significantly greater number of anaerobic colonies compared with aerobic colonies (Table 10), which is consistent with previous reports.[19] After 5 days or 7–8 days of antibiotic therapy, all colony counts were significantly reduced; there were no significant differences between the number of aerobes or anaerobes. Each postdecontamination colony count represented at least a 93% reduction in colony-forming units per gram of stool when compared with controls.

The mean portal ammonia concentration was 306 ± 15 μmol/L, significantly reduced from the basal concentration in the nonantibiotic-treated animals (Table 11). The arterial ammonia concentration was not significantly altered by antibiotic therapy. The diminished portal ammonia concentration resulted in a significant narrowing of the ammonia PV-A concentration gradient compared with nonantibiotic-treated animals. No alteration occurred in arterial or portal glutamine concentration nor in the PV-A concentration difference. However, both arterial and portal glutamate concentrations were significantly lower than in nonantibiotic-treated animals, but the PV-A concentration gradient was unaltered. All the PV-A concentration differences were significantly different from zero as the gastrointestinal tract continued to extract or release these substrates.

Mean basal portal blood flow measured in six studies was 36 ± 5 mL/min/kg, which is within the range of measurements in nonantibiotic-treated animals (NS when compared with nonantibiotic-treated animals). For glutamine and glutamate, exchange rates were comparable to those in nonantibiotic-treated animals. In contrast, basal gastrointestinal ammonia production was significantly reduced in the decontaminated dogs compared with the nonantibiotic-treated animals.

After the administration of blood by orogastric tube, a rapid rise in portal ammonia concentration occurred by 30 minutes and remained significantly elevated over the initial basal concentration for up to 150 minutes (Table 12). The ammonia PV-A concentration difference widened significantly at 60 and 90 minutes, whereas a transient increase in arterial ammonia concentration occurred at 150 minutes. Portal blood flow remained constant throughout the study period. Intestinal ammonia production increased significantly at 30 minutes and

again at 90 minutes. In contrast to the nonantibiotic-treated dogs who received blood meals, no significant changes occurred in the arterial or portal concentrations of glutamine or glutamate, nor in their PV-A concentration gradients or rates of gastrointestinal exchange (Table 13).

After the administration of blood by rectal catheter, portal vein ammonia concentration and PV-A concentration difference did not change significantly from basal measurements, nor did either value increase with time (Table 12). A transient but significant elevation in arterial ammonia occurred at 60 minutes. Portal blood flow remained constant throughout the study period. Intestinal ammonia production remained constant and did not change significantly with time. Portal vein glutamine and glutamate did not change significantly from basal values, nor was there a change in the PV-A concentration gradients (Table 13). Gastrointestinal exchange of these substrates remained constant. Arterial glutamine concentration decreased significantly from initial basal concentrations at 90 and 210 minutes. No change occurred in arterial glutamate concentration.

The basal-to-peak response for portal ammonia concentration, PV-A concentration difference, and gastrointestinal ammonia production were significantly greater after blood meals compared with blood enemas after gut decontamination. No significant difference was observed in the basal-to-peak response for arterial ammonia concentration (Table 14). A significantly greater total quantity of ammonia was produced after meals than after enemas. No significant differences were observed in the time of the peak responses between the two groups.

The ammonia production curves after blood meals were similar with or without gut decontamination (Fig. 3). Both responses were characterized by early elevations in gastrointestinal ammonia production compared with the flat curve observed after water meals. Each trapezoidal curve returned to a value not significantly different from its respective basal release rate by 150 minutes as shown in Tables 2 and 12. After gut decontamination, blood enemas did not alter basal ammonia production (Fig. 4).

Discussion

In order to study the mechanisms of increased ammonia production after upper gastrointestinal hemorrhage, many investigators have administered blood meals to dogs with chronic Eck-fistulas.[6,19,20] After gastric blood administration, a slow gradual rise in peripheral blood ammonia concentration usually occurred, suggesting that the colon was the source of the ammonia generated. However, the rate of portal ammonia generation was rarely quantitated and only peripheral blood ammonia concentrations were monitored. Moreover, relatively large volumes of blood (200–700 mL) were administered in many of the studies, which may have stimulated small bowel hyperperistalsis and delivered undigested blood to the colon. Such an experimental approach did not allow a distinction to be made between the ammonia produced in the upper and lower gastrointestinal tract.

In this study, we developed protocols that quantitated the rate of portal ammonia production in healthy, chronically catheterized animals. A small volume of

blood was administered by meal and by enema (average volume approximately 120 mL), allowing us to differentiate between ammonia produced in the upper and lower gastrointestinal tract. The same quantity of ammonia was produced after blood was administered into the stomach or the colon, but the mechanisms involved appear different. For example, gastric administration resulted in a prompt peak (60 minutes) in intestinal ammonia production, whereas the time of peak production after blood enemas was severely delayed (150 minutes). This attenuated response after blood enemas was not due to the inability of bacteria to deaminate whole protein, for amino acid administration by enema produced similar rates of ammonia generation.

The small volume and caloric load contained in the blood meal was unlikely to alter the intestinal motility pattern of the small bowel.[21] The time of propagation of phase 3 of the migrating motor complex from the stomach to the terminal ileum in dogs ranges from 105 to 134 minutes,[22] a time too long to account for the rapid rise in ammonia production occurring after the blood meal if the ammonia were generated in the colon. The rise in portal concentration of ammonia after the blood meal mimicked absorption data of other markers of small bowel function, such as glucose or D-xylose.[23] Glutamine and glutamate absorption occurred at the same time ammonia production increased after blood meals. Because amino acids and peptides are almost exclusively absorbed in the upper jejunum by active transport processes,[24] this association also indicates that the small bowel was the source of the ammonia generated. The early rise in intestinal ammonia production appears to be due to the metabolism of ammoniagenic amino acids by enterocytes of the small intestine, a process that liberates ammonia.

The rise in portal and arterial glutamine concentrations after blood meals is consistent with the work of other investigators who have observed elevations in alpha-amino nitrogen and amino acids after a protein meal.[25,26] The diminished intestinal glutamine uptake observed after blood meals may be secondary to the inhibition of extraction of arterial glutamine by the bowel when glutamine and glutamate are present in the lumen.[9] The rise in portal glutamate concentration observed after blood meals was not observed in studies of amino acid metabolism after a horsemeat meal.[26] Our

findings suggest that glutamate derived either from the blood meal or from the deamidation of glutamine is not entirely converted to other substances such as alanine because it is metabolized in the cells of the gastrointestinal tract of the small bowel.

Portal blood flow did not change after blood or amino acid meals, an observation consistent with previous reports that portal blood flow was unaltered after protein administration to awake dogs.[25] In contrast, portal blood flow increased after the instillation of protein hydrolysates into the duodenum of anesthetized dogs.[27] If such an increase in portal blood flow occurred in our studies but was undetected, the magnitude of this early rise in intestinal ammonia release after blood meals would be greater, not less, than the values reported.

After blood enemas, portal blood ammonia concentration gradually rose and peaked at 150 minutes. Although the total quantity of ammonia produced was generally comparable to that of the blood meal, the am-

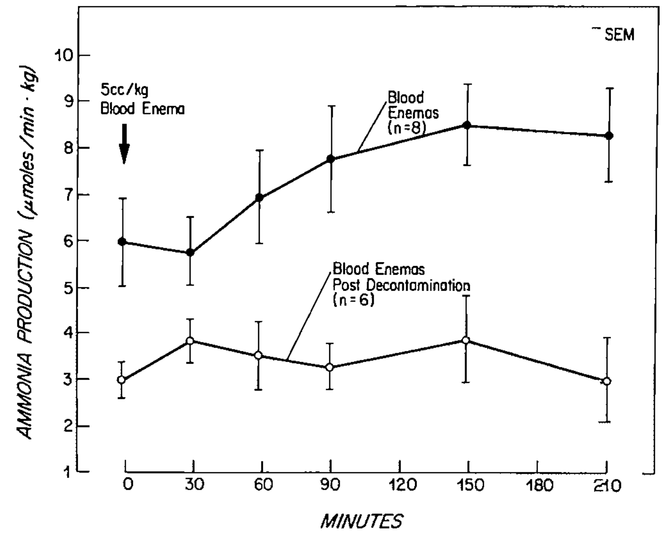

FIG. 4. The increase in ammonia production after blood enemas was greatly attenuated by intestinal decontamination.

monia production after blood enemas did not return to normal values by the end of the study. It is possible that additional measurements over several additional hours would have revealed persistent ammonia production for a longer period. Unlike the blood meals, there was no uptake of amino acids after the blood enemas. This is consistent with the proposed mechanism of intraluminal bacterial hydrolysis and slow diffusion of ammonia from the colon into the blood stream.

After 5–8 days of antibiotic administration, basal portal ammonia concentration, ammonia PV-A concentration difference, and basal ammonia production were all reduced, which are consistent with findings previously reported by others.[4] Antibiotic therapy abolished the gradual rise in ammonia production after blood enemas, which supports the concept that the delayed response in ammonia production after colonic blood administration is mediated by microbe enzymatic hydrolysis of the intraluminal nitrogen substrate found in the blood. However, antibiotic therapy did not attenuate the early rise in ammonia production after the blood meal, despite a greater than 93% reduction in the bowel microflora. Because of the relative paucity of bacteria in the upper gastrointestinal tract of mammals compared with the colon[28] and our failure to diminish the production from the upper gastrointestinal tract, it appears that micro-organisms play a relatively insignificant role in ammonia production by the small bowel. Gut decontamination decreased basal ammonia production of the intestinal tract in association with reducing the number of colonic bacteria. However, the small bowel ammonia production persisted after gastric blood administration, suggesting that nonmicrobial mechanisms are involved in this process.

An alternative hypothesis, however, has been advanced to explain the effect of intestinal antibiotics.[29] Van Leeuwen and associates have quantitated the rate of ammonia produced by isolated enterocytes and colocytes. Addition of lactulose or neomycin to these *in vitro* systems attenuated ammonia production. This response was observed in tissue harvested from either conventional or germ-free animals. The authors conclude that these substances reduce ammonia production by interfering with intracellular glutamine metabolism. Although our *in vivo* studies were not designed to parallel these *in vitro* experiments, we cannot exclude this hypothesis as a possible explanation for the attenuation of ammonia production in the decontaminated animals after blood enemas. However, since ammonia production from the upper gastrointestinal tract was unaffected by antibiotic administration, this direct effect on enterocyte metabolism did not occur in our animals. It should be noted that lactulose was not given as part of our decontamination regimen.

Gut decontamination had no effect on basal intestinal exchange of glutamine and glutamate. Although glutamine concentrations were not altered, both arterial and portal glutamate concentrations were diminished. The hepatic synthesis of glutamate depends on the availability of its precursors ammonia and alpha-ketoglutarate. The diminished glutamate levels may reflect the decrease in the gastrointestinal ammonia production.[30] After the administration of the blood meal to decontaminated animals, the absorption of glutamine and glutamate was attenuated. The effect may be related to the administration of antibiotics by the enteral route. It has been reported that neomycin decreases the concentrations of selected enzymes within the enterocyte.[29] Neomycin administration is also associated with a reversible malabsorption syndrome, which may explain the failure of glutamine and glutamate to rise after the blood meal.[31] Although the specific role of these antibiotics in decreasing the portal concentrations of glutamine after a blood meal is not known, the early rise in intestinal ammonia production in decontaminated animals after a blood meal suggests that glutamine is absorbed and utilized by the enterocyte to generate ammonia. Further studies are needed to define the interaction among intraluminal antibiotics, enterocyte metabolism, and intestinal ammonia production.

It is believed that hyperammonemia plays some role in the cause of hepatic encephalopathy, although the exact relationship between elevated ammonia concentration in arterial blood and central nervous system dysfunction remains unknown. However, administration of agents that reduce the microbial flora or alter intraluminal ammonia production is common clinical practice. Although this treatment may be effective therapy for the ammonia produced by the colon, it has little impact on ammonia produced by the small intestine. Therapy that specifically decreases small bowel ammonia production is necessary if hyperammonia after upper gastrointestinal hemorrhage is to be controlled.

In summary, intestinal ammonia production increases within the first 60 minutes after a blood meal. This response was mimicked by the gastric administration of ammoniagenic amino acids. The increased ammonia production after blood meals was associated with amino acid absorption, which indicates the small intestine was participating in this response. In contrast, blood administered by enema resulted in a gradual rise in ammonia production. This response was not due to a lack of predigestion of protein precursors that are presented to the colon from the upper gastrointestinal tract, for amino acid enemas elicited responses similar to blood instillation. Gut decontamination reduced basal ammonia production and ablated the rise in ammonia production after colonic blood administration. Gut decontamination had no effect on ammonia production after a blood meal.

The increased ammonia production after upper gastrointestinal hemorrhage results from the generation of ammonia by both the small intestine and colon. The enterocytes of the small bowel absorb and metabolize ammoniagenic amino acids derived from blood proteins and produce ammonia. Bacteria of the colon hydrolyze the blood reaching the distal bowel and liberate ammonia. Although gut decontamination may reduce ammonia production by the colon, it is not specific therapy directed toward enterocyte amino acid metabolism and therefore does not alter the ammonia produced by the small intestine.

Five days after thyroidectomy (Tx) or sham-Tx in young male Sprague-Dawley rats, sepsis was induced by cecal ligation and puncture (CLP). Control animals underwent laparotomy and manipulation of the cecum without ligation or puncture. Sixteen hours after CLP or laparotomy, protein synthesis and degradation were measured in incubated extensor digitorum longus (EDL) and soleus (SOL) muscles by determining rate of ^{14}C-phenylalanine incorporation into protein and tyrosine release into incubation medium, respectively. Triiodothyronine (T_3) was measured in serum and muscle tissue. Protein synthesis was reduced by 39% and 22% in EDL and SOL, respectively, 16 hours after CLP in sham-Tx rats. The response to sepsis of protein synthesis was abolished in Tx rats. Protein breakdown was increased by 113% and 68% in EDL and SOL, respectively, 16 hours after CLP in sham-Tx animals. The increase in muscle proteolysis during sepsis was blunted in hypothyroid animals and was 42% and 49% in EDL and SOL, respectively. T_3 in serum was reduced by sepsis, both in Tx and sham-Tx rats. T_3 in muscle, however, was maintained or increased during sepsis. Abolished or blunted response of muscle protein turnover after CLP in hypothyroid animals may reflect a role of thyroid hormones in altered muscle protein metabolism during sepsis. Reduced serum levels of T_3, but maintained or increased muscle concentrations of the hormone, suggests that increased T_3 uptake by muscle may be one mechanism of low T_3 syndrome in sepsis, further supporting the concept of a role for thyroid hormone in metabolic alterations in muscle during sepsis.

ACCELERATED BREAKDOWN and inhibited synthesis of skeletal muscle protein have been reported both in hyperthyroidism[1-4] and sepsis.[5-8] This may seem paradoxical, since circulating levels of thyroid hormones are reduced in critically ill and septic patients,[9,10] and may indicate that thyroid hormones are not involved in the pathogenesis of altered muscle protein turnover in sepsis. Recent studies, however, suggested that one mechanism of low serum concentrations of thyroid hormones in sepsis may be enhanced tissue uptake.[11,12] Thus, total cellular and hepatic uptake of thyroxine (T_4) was increased in septic monkeys,[11] and concentration of triiodothyronine (T_3) was maintained or increased in kidney and liver tissue during endotoxemia in rats, despite decreased circulating T_3 levels.[12]

T_3 concentrations in muscle tissue during sepsis have not been reported, and it is not known if thyroid hormone plays a role in altered muscle protein metabolism in this condition. The purpose of this investigation was to study muscle T_3 levels during sepsis and to measure protein turnover rates in incubated skeletal muscles from septic euthyroid and hypothyroid rats. Preliminary results of this study were presented previously.[13]

Materials and Methods

Thyroidectomy (Tx) or sham thyroidectomy (sham-Tx) was performed in young, male Sprague-Dawley rats, weighing 45–50 g (Zivic-Miller, Allison Park, PA). To compensate for possible damage to the parathyroid glands during Tx, rats received drinking water supplemented with 1% calcium lactate after Tx. Small animals were used because they have thin extensor digitorum longus (EDL) and soleus (SOL) muscles, enabling measurement of protein turnover in incubated muscles.[14]

One group of rats was killed 5 days after Tx or sham-Tx for determination of T_3 and calcium levels in serum. In other rats, sepsis was induced between 5:00 P.M. and 6:00 P.M. on the 5th day after Tx or sham-Tx, and 16 hours later, T_3 in muscle and serum and protein turnover rates in incubated EDL and SOL muscles were

measured. Only T_3 was determined because this is biologically the most active form of thyroid hormones.

Sepsis was induced by cecal ligation and puncture (CLP) as described previously.[15] Under light ether anesthesia, laparotomy was performed and the cecum was ligated and punctured twice with an 18-gauge needle. Nonseptic control rats had sham operation, in which a laparotomy was performed and the cecum was manipulated but not ligated or punctured. All rats received saline (5 mL/100 g) subcutaneously on the back for resuscitation and were fasted with free access to water after the operative procedures. After 16 hours, four groups of rats were studied, *i.e.*, sham-Tx controls, sham-Tx CLP, Tx controls, and Tx CLP. All animals, from which muscles were harvested, weighed 70 g or less.[14]

Measurement of Protein Synthesis and Degradation in Incubated Skeletal Muscles

Under light ether anesthesia, EDL and SOL muscles were dissected with intact tendons, weighed, and preincubated for 30 minutes in 3 mL of a medium consisting of Krebs-Henseleit bicarbonate buffer (pH 7.4) with glucose (10 mM). The medium was saturated with O_2:CO_2 (95:5) and incubation was performed in a shaking water bath at 37 C. After preincubation the muscles were gently blotted and transferred to fresh medium. For the study of protein synthesis, the medium was supplemented with [^{14}C]-phenylalanine (0.5 mM; 0.05 uCi/mL) and the amount of amino acid incorporated into protein during incubation for 2 hours (μmol Phe × gww^{-1} × $2h^{-1}$) was determined as described in detail elsewhere.[8] For the study of protein degradation, the medium was supplemented with cycloheximide (0.5 mM) to prevent reincorporation of amino acids, and protein degradation rate was estimated from amount of tyrosine released into the incubation medium during 2 hours (μmol Tyr × gww^{-1} × $2h^{-1}$). Tyrosine was determined according to Waalkes and Udenfriend.[16] This method for measurement of protein degradation rate was described previously.[17–19] Since tyrosine is not synthesized or metabolized by skeletal muscle, and tissue concentration of free tyrosine remained constant during incubation, both in normal and septic muscles,[7] it is possible to estimate protein degradation rate by measuring release of tyrosine into the incubation medium.

Determination of Serum and Muscle T_3 Levels

Under light ether anesthesia, blood was drawn by heart puncture and one SOL muscle was dissected as described above. The muscle was immediately frozen on dry ice, weighed (muscle weights varied between 25 and 30 mg) and homogenized in 0.15 mL of saline with 10^{-3} mM propylthiouracil (Sigma, St. Louis, MO) at 0–4 C in a micro-homogenizer (Kontes Glassware, Vineland, NJ). A small amount of ^{125}I-T_3 was added to the homogenate for determination of recovery. Ethanol (0.3 mL of 96% ethanol) was added to the homogenate and thoroughly mixed on a Vortex Mixer (American Scientific Products, McGaw Park, IL) for 1 minute. After centrifugation (1500 g for 20 minutes) the extraction of the pellet with ethanol was repeated twice. The supernatants were then pooled and recentrifuged at 1500 g for 20 minutes. An aliquot of the ethanol extract was dried under a stream of nitrogen. The residue was dissolved in 50 μL of T_3 free serum and counted to determine recovery, which was 91 ± 2% (N = 44).

TABLE 1. *T_3 and Calcium Concentrations in Serum 5 Days after Tx or Sham-Tx in Rats*

	Sham-Tx (N = 6)	Tx (N = 6)
T_3 (ng/dL)	118 ± 7.9	46 ± 2.7*
Calcium (mg/dL)	10.2 ± 0.22	8.1 ± 0.17*

* $p < 0.01$ *vs.* sham-Tx (Wilcoxon rank sum test).

For determination of T_3 in blood serum and muscle extract, a radioimmunoassay was used (Diagnostic Products Corporation, Los Angeles, CA). To maximize sensitivity of the assay, the following modified protocol was established: 50 μL of T_3 standard, serum sample, or muscle extract was incubated with 50 μL of ^{125}I-T_3 and 50 μL of T_3 antiserum (diluted twice with water) at 4 C for 16–18 hours, followed by addition of 500 μL of goat antirabbit IgG, centrifugation, and counting of the precipitate. The minimum detection limit of the assay was 2.5 pg per tube with an interassay coefficient of variation less than 6.3%.

Statistics

Results are presented as mean ± SEM. Unless stated otherwise, significant differences between group means were determined by analysis of variance (ANOVA) followed by Duncan's multiple range test. A p value less than 0.05 was considered significant.

Results

Serum T_3 5 days after sham-Tx was 118 ± 7.9 ng/dL, which is in line with previous studies in young Sprague-Dawley rats,[20] but higher than reported in bigger rats.[12] Five days after Tx, T_3 in serum was reduced to about one third of control value (Table 1). Despite the fact that thyroidectomized animals received drinking water supplemented with calcium lactate, serum calcium was reduced 5 days after Tx (Table 1).

The survival rate was approximately 20% 16 hours after CLP with no significant difference between Tx and

TABLE 2. *Body Temperature (C) 16 Hours after Sham-laparotomy (Control) or CLP in Euthyroid (Sham-Tx) and Hypothyroid (Tx) Rats**

	Control	CLP
Sham-Tx	37.8 ± 0.15 (8)	37.0 ± 0.51 (8)
Tx	36.9 ± 0.29 (8)	35.0 ± 0.49† (13)

* Numbers in parentheses indicate number of rats.
† $p < 0.05$ *vs.* all other groups (ANOVA).

sham-Tx rats. There was no mortality rate among control (sham-CLP) rats. All surviving septic rats showed clinical signs of illness in the form of diarrhea, piloerection, and exudate around the eyes, with no apparent differences between euthyroid and hypothyroid rats.

Body temperature was somewhat lower in septic, euthyroid rats than in nonseptic euthyroid rats (Table 2), although the difference was not statistically significant. Similar results were reported in recent studies from this laboratory,[7,8] and probably reflect the small-sized rats used in this study. Regulation of body temperature is different in small rodents than in bigger animals due to the relatively high surface area to volume ratio,[21] which probably explains why sepsis was not associated with hyperthermia in this study. As expected, body temperature was lower in hypothyroid than in euthyroid rats, and temperature was further decreased in hypothyroid, septic rats (Table 2).

Serum T_3 was significantly reduced 16 hours after CLP in sham-Tx rats (Fig. 1), confirming previous results of a low T_3 syndrome after injury and sepsis.[9,10,12] Also, in hypothyroid rats (Tx), serum T_3 was significantly decreased during sepsis (Fig. 1).

The difference between nonseptic and septic groups in Tx rats was also statistically significant ($p < 0.05$ by ANOVA).

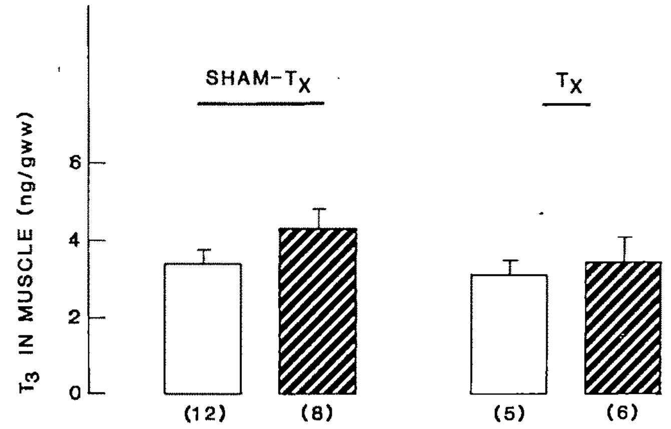

FIG. 2. Concentration of T_3 in SOL muscles from sham-Tx and Tx rats 16 hours after sham-CLP (open bars) or CLP (hatched bars). Numbers in parentheses indicate number of rats.

T_3 in SOL muscle from euthyroid (sham-Tx) control rats was 3.42 ± 0.22 ng/g tissue, which is in agreement with T_3 concentrations in red muscle, reported previously.[22] The mean value of muscle T_3 was 25% higher in septic, euthyroid rats than in nonseptic, euthyroid rats (Fig. 2). This difference, however, was not statistically significant by ANOVA. The range of T_3 concentrations in septic muscles was 2.67–6.06 ng/g and in nonseptic muscles was 2.38–4.71 ng/g. Muscle T_3 in hypothyroid control and septic rats was similar to the hormone concentration in muscle from euthyroid, nonseptic rats (Fig. 2).

Protein synthesis rate in incubated EDL and SOL muscles was reduced by 39% and 22%, respectively, 16 hours after CLP in euthyroid rats (Table 3). In previous studies, both increased[23,24] and reduced[6] synthetic rates were reported in sepsis. In a recent communication from this laboratory, protein synthesis in incubated rat EDL muscles was unchanged, whereas synthetic rate in SOL muscles was reduced 8 hours and 16 hours after CLP, although not significantly.[8] Thus, the effect of sepsis on muscle protein synthesis is not as consistent as the stimulating effect on protein breakdown. In nonseptic, hypothyroid rats, protein synthesis rate was reduced in EDL but was not altered in SOL (Table 3). In contrast to euthyroid rats, no significant reduction of protein synthesis occurred in EDL or SOL during sepsis in Tx rats (Table 3).

Protein breakdown rate in incubated EDL and SOL muscles was increased by 113% and 68%, respectively, 16 hours after CLP in euthyroid rats (Table 4), similar to previous reports from this laboratory.[7,8] Protein breakdown rates in EDL and SOL muscles in nonseptic, hypothyroid rats were similar to control values in sham-Tx rats. In other studies, reduced protein degradation was observed in animals in which Tx resulted in nonmea-

surable serum T_3 levels.[25] The increase in muscle proteolysis during sepsis was blunted in the hypothyroid rats compared with the increase seen in euthyroid rats, and was 42% and 49% in EDL and SOL, respectively (Table 4). The difference in proteolytic rates between septic hypothyroid and septic euthyroid rats was statistically significant.

Discussion

This study demonstrated that the sepsis-induced inhibition of muscle protein synthesis and increase in muscle protein breakdown were abolished or blunted in hypothyroid rats. The results may be consistent with the hypothesis that thyroid hormones play a role in altered muscle protein metabolism during sepsis, although other interpretations must be considered as well. The data also showed that changes in serum T_3 levels did not reflect alterations in muscle concentrations of the hormone, since T_3 in muscle was unchanged or increased after Tx and during sepsis, despite reduced serum levels.

In a previous study, serum T_4 was reduced to 13% of control values 3 days after thyroidectomy in rats.[26] Since disappearance time from serum of T_3 is shorter than that of T_4,[27] our results of serum T_3 levels 5 days after Tx, *i.e.*, approximately one third of control values, suggest that the thyroid gland was not completely removed in our rats. This probably reflected technical difficulties due to the small size of the animals, further supported by the damage to the parathyroid glands, as indicated by reduced serum calcium levels.

Survival rates were not significantly different in septic euthyroid and hypothyroid rats in this study. In a previous report, the survival rate after CLP in rats was reduced from 65% to 30% in hypothyroid rats.[26] Comparison of these results is difficult, however, because in that study bigger rats were used and sepsis was induced 2 weeks after Tx, at which time serum levels of thyroid hormones were too low to be measurable.[26]

Different mechanisms of reduced circulating levels of thyroid hormones after injury and sepsis were suggested previously, *e.g.*, reduced thyroid function,[27,28] defective binding of the hormones to carrier proteins,[29] and an impaired 5′-deiodination of T_4 to T_3.[30] Accelerated peripheral disposal of thyroid hormones was demonstrated during bacterial infections and fever,[31] possibly reflecting increased deiodination of the hormones by phagocytic cells[32] or increased uptake in different tissues.[11,12] The increased T_3 concentrations in septic muscle in the current study, although not statistically significant, may reflect enhanced uptake of the hormone in skeletal muscle during sepsis. Evidence of specific and concentrative transport systems for intracellular uptake of T_3 in different tissues was presented recently.[33]

Another mechanism for maintaining or elevating muscle T_3 levels in sepsis might be an increased conversion of T_4 to T_3. Results demonstrating that T_4 to T_3 conversion occurs in skeletal muscle were reported previously.[34] The same study, however, showed that the amount of T_3 taken up by muscle during a 2-hour period was approximately 200 times greater than the amount converted from T_4 during the same period. Thus, alterations in cellular uptake are probably more important than changes in T_4 to T_3 conversion for the regulation of muscle T_3 levels. Based on the T_3 concen-

trations in serum and muscle found in this study, the calculated amount of T_3 in the total muscle pool was 20–30 times greater than total serum T_3, suggesting that even a small alteration in muscle T_3 uptake could greatly influence serum levels.

The current observation that muscle concentration of T_3 was maintained 5 days after thyroidectomy is in agreement with a recent report by Obregon et al.[35] In that study thyroid hormones were clearly detectable in different tissues, including muscle, up to 4 months after thyroidectomy in rats. Thus, not only does muscle contain a much larger pool of thyroid hormones, but the disappearance rate of the hormones is also substantially lower in muscle than in serum. This further suggests that consideration of tissue levels, in addition to serum concentrations, is important when the metabolic effects of thyroid hormones are studied.

Possible mediator(s) and mechanism(s) of accelerated muscle protein breakdown in sepsis have been extensively studied in recent years. Reports by Clowes et al. suggested that a circulating peptide called proteolysis-inducing factor (PIF), which is probably a split product of interleukin-1 (IL-1), is the mediator of enhanced muscle proteolysis after injury and sepsis.[5,36,37] Studies by Watters et al., however, did not confirm a role of IL-1 or PIF for accelerated muscle protein breakdown,[38] but suggested that the combined effect of the catabolic hormones cortisol, glucagon, and epinephrine may be responsible for metabolic alterations in trauma and sepsis.[39] It is possible that different types of stimuli are required for the full manifestation of host responses to severe injury and infection.[40]

The result in this study of blunted increase in muscle protein breakdown in hypothyroid rats may be interpreted as indicating that thyroid hormones play a role in sepsis-induced muscle proteolysis. The fact that protein breakdown was increased to some extent in septic, hypothyroid rats, in which muscle T_3 was not elevated, suggests, however, that thyroid hormones are not a major mediator of protein breakdown in sepsis. It is possible that the results reflected an interaction between thyroid hormones and other metabolic mediators, such as catecholamines.[41,42]

The mechanism of reduced protein synthesis in sepsis has not been extensively studied, probably reflecting that the response of protein synthesis is not consistent, and that the major effect of sepsis on muscle is a dramatic acceleration of protein breakdown. Also, in the hyperthyroid state, the major event in skeletal muscle was an acceleration of proteolysis, whereas protein synthesis was unchanged,[2,3] increased,[43] or reduced.[4]

The inability of the hypothyroid rats to respond normally to sepsis in the current study is in agreement with a recent report by Moley et al.[26] In that study, total body oxygen consumption was increased by 13% during early sepsis in normal rats, but was depressed by 20% in septic, hypothyroid rats. Liver blood flow, which increased after induction of sepsis in euthyroid rats, was unchanged in hypothyroid rats. Hepatic mitochondrial respiratory control ratio was also affected by the hypothyroid state.[26] Thus, thyroid hormones may be of importance for various metabolic responses to sepsis. Since serum concentrations of thyroid hormones are reduced both in sepsis and after Tx, but the metabolic changes are opposite, the interaction between thyroid hormone and sepsis may be best explained by tissue levels of the hormone.

Although the current results suggest a role of thyroid hormone in accelerated muscle proteolysis during sepsis, other interpretations of the results may also be considered. Increased protein breakdown after the addition of calcium *in vitro* to incubated rat skeletal muscles was reported previously.[44] Hence, it could be argued that the reduced protein degradation in septic, hypothyroid rats reflected reduced serum calcium levels. A recent study demonstrated, however, that the effect of calcium on muscle protein breakdown is mainly an *in vitro* phenomenon, and muscle protein degradation rates were similar in patients with different serum calcium levels.[45]

In addition to lower serum concentration of T_3 and calcium, body temperature was reduced in thyroidectomized rats. In a recent study, protein degradation in incubated rat skeletal muscles was decreased when the temperature of the incubation medium was reduced.[46] It is not likely, however, that the blunted increase in muscle proteolysis in the hypothyroid rats was due to reduced body temperature, since in recent studies we found that protein breakdown was greatly increased in septic rats, despite hypothermia.[7,8] Similarly, results were reported suggesting that the hypermetabolic response to sepsis was independent of changes in body temperature.[47]

Tx is known to reduce the amount of growth hormone in the pituitary and serum of rats.[48] Protein turnover in skeletal muscle is influenced by growth hormone.[49] However, since serum concentration of growth hormone remained within control range for at least 7 days after Tx,[48] it is not likely that results in the current study were caused by altered growth hormone levels.

Decreased blood volume and cardiac output was reported in hypothyroidism.[50] Thus, despite that all animals were volume resuscitated after induction of sepsis, it is possible that inability to develop a hyperdynamic phase during sepsis might be a reason for the blunted metabolic response in hypothyroid rats.

In conclusion, the current study suggests that thyroid hormones play a role in altered muscle protein turnover during sepsis. Further experiments are required, however, to rule out the possibility that the results reflected other effects of Tx than reduced T_3 levels. In future studies, the interaction between T_3 and other possible mediators of protein breakdown in sepsis, such as IL-1 and the catabolic hormones, would be of interest to elucidate.

PIPRACIL®
STERILE PIPERACILLIN SODIUM FOR
INTRAVENOUS AND INTRAMUSCULAR USE

A Brief Summary
Consult package insert for full prescribing information.

INDICATIONS AND USAGE: Therapeutic. PIPRACIL is indicated for the treatment of the following serious infections caused by susceptible strains of the designated organisms: Intra-abdominal, urinary tract, gynecologic, lower respiratory tract, skin and skin structure, bone and joint, gonococcal infections, and septicemia.

Prophylaxis. PIPRACIL is also indicated for prophylactic use in surgery including intra-abdominal (gastrointestinal and biliary) procedures, vaginal hysterectomy, and cesarean section.

CONTRAINDICATIONS: A history of allergic reactions to any of the penicillins and/or cephalosporins.

WARNINGS: Serious and occasionally fatal hypersensitivity (anaphylactic) reactions have been reported in patients receiving therapy with penicillins. These reactions are more apt to occur in persons with a history of sensitivity to multiple allergens.

There have been reports of patients with a history of penicillin hypersensitivity who have experienced severe hypersensitivity reactions when treated with a cephalosporin. Before initiating therapy with PIPRACIL® sterile piperacillin sodium, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, and other allergens. If an allergic reaction occurs during therapy with PIPRACIL, the antibiotic should be discontinued. The usual agents (antihistamines, pressor amines, and corticosteroids) should be readily available. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN AND INTRAVENOUS CORTICOSTEROIDS AND AIRWAY MANAGEMENT INCLUDING INTUBATION SHOULD ALSO BE ADMINISTERED AS NECESSARY.

PRECAUTIONS: General. While PIPRACIL possesses the characteristic low toxicity of the penicillin group of antibiotics, periodic assessment of organ system functions including renal, hepatic, and hematopoietic during prolonged therapy is advisable. Bleeding manifestations have occurred in some patients receiving β-lactam antibiotics including piperacillin. These reactions have sometimes been associated with abnormalities of coagulation tests such as clotting time, platelet aggregation, and prothrombin time and are more likely to occur in patients with renal failure. If bleeding manifestations occur, the antibiotic should be discontinued and appropriate therapy instituted.

The possibility of the emergence of resistant organisms which might cause superinfections should be kept in mind, particularly during prolonged treatment. If this occurs, appropriate measures should be taken.

As with other penicillins, patients may experience neuromuscular excitability or convulsions if higher than recommended doses are given intravenously.

PIPRACIL is a monosodium compound containing 1.85 milliequivalents of Na^+ per gram. This should be considered when treating patients requiring restricted salt intake. Periodic electrolyte determinations should be made in patients with low potassium reserves, and the possibility of hypokalemia should be kept in mind with patients who have potentially low potassium reserves and who are receiving cytotoxic therapy or diuretics.

Antimicrobials used in high doses for short periods to treat gonorrhea may mask or delay the symptoms of incubating syphilis. Therefore, prior to treatment, patients with gonorrhea should also be evaluated for syphilis. Specimens for darkfield examination should be obtained from patients with any suspected primary lesion and serologic tests should be performed. In all cases where concomitant syphilis is suspected, monthly serological tests should be made for a minimum of four months.

As with other semisynthetic penicillins, PIPRACIL therapy has been associated with an increased incidence of fever and rash in cystic fibrosis patients.

Drug Interactions. The mixing of PIPRACIL with an aminoglycoside *in vitro* can result in substantial inactivation of the aminoglycosides.

Pregnancy—Pregnancy Category B. Although reproduction studies in mice and rats performed at doses up to four times the human dose have shown no evidence of impaired fertility or harm to the fetus, safety of PIPRACIL use in pregnant women has not been determined by adequate and well-controlled studies. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. It has been found to cross the placenta in rats.

Nursing Mothers. Caution should be exercised when PIPRACIL is administered to nursing mothers. It is excreted in low concentrations in milk.

Pediatric Use. Dosages for children under the age of 12 have not been established. The safety of PIPRACIL in neonates is not known. In dog neonates dilated renal tubules and peritubular hyalinization occurred following administration of PIPRACIL.

ADVERSE EFFECTS: PIPRACIL is generally well tolerated. The most common adverse reactions have been local in nature, following intravenous or intramuscular injection. The following adverse reactions may occur:

Local Reactions. Thrombophlebitis (4%), pain, erythema, and/or induration at the injection site (2%) and, less frequently, ecchymosis, deep vein thrombosis, hematomas.

Gastrointestinal. Diarrhea and loose stools (2%); less frequently, vomiting, nausea, increases in liver enzymes (LDH, SGOT, SGPT), hyperbilirubinemia, cholestatic hepatitis, bloody diarrhea, and, rarely, pseudomembranous colitis.

Hypersensitivity Reactions. Anaphylactoid Reactions (see WARNINGS). Rash (1%); less frequently, pruritus, vesicular eruptions, positive Coombs tests.

Renal. Elevations of creatinine or BUN and, rarely, interstitial nephritis.

Central Nervous System. Headache, dizziness, fatigue.

Hemic and Lymphatic. Reversible leukopenia, neutropenia, thrombocytopenia, and/or eosinophilia have been reported. As with other β-lactam antibiotics, reversible leukopenia (neutropenia) is more apt to occur in patients receiving prolonged therapy at high dosages or in association with drugs known to cause this reaction.

Serum Electrolytes. Individuals with liver disease, or individuals receiving cytotoxic therapy or diuretics, were reported rarely to demonstrate a decrease in serum potassium concentrations with high doses of piperacillin.

Skeletal. Rarely, prolonged muscle relaxation.

Other. Superinfection, including candidiasis. Hemorrhagic manifestations.

Lymphocyte Participation in Wound Healing

Morphologic Assessment Using Monoclonal Antibodies

RHONDA S. FISHEL, M.D., ADRIAN BARBUL, M.D., WILLIAM E. BESCHORNER, M.D.,* HANNAH L. WASSERKRUG, B.A., and GERSHON EFRON, M.D.

From the Department of Surgery, Sinai Hospital of Baltimore and the Department of Pathology, Johns Hopkins School of Medicine, Baltimore, Maryland*

To investigate lymphocyte participation in wound healing, the migration of T lymphocyte subsets into healing wounds and subcutaneously implanted polyvinyl alcohol sponges was studied. Frozen sections of 5-, 7-, and 10-day-old incisional wounds and sponges from Lewis rats were stained with mouse anti-rat monoclonal antibodies. Cellular staining to OX1 (all leucocyte), W3/25 (helper/effector T lymphocytes), and OX8 (suppressor/cytotoxic T lymphocytes) was quantitated in two arbitrarily defined areas based on maximal cellular infiltration: (1) the superficial wound, down to and including the papillary dermis, and (2) the deep wound, the reticular dermis. Five-day wounds were significantly more cellular than 10-day wounds in the deep portion ($p < 0.05$) and somewhat more cellular in the superficial section ($p < 0.10$). Approximately 2:1 W3/25 to OX8 ratios were noted for wound strips on all days. At 5 and 10 days there are twice as many W3/25 and OX8 labeled cells in the deep wound as in the superficial portion. At 7 days there is a peak in surface W3/25 and OX8 lymphocytes, whereas the deep population remains constant. Seven- and 10-day sponge granulomas demonstrate ratios similar to the wound strips (5-day sponge lymphocytic infiltration was insufficient to count). The data demonstrate that lymphocyte subpopulation participation in wound healing is a dynamic and distinctive process.

THE NORMAL HEALING OF WOUNDS involves a cascade of cellular events. Although lymphocytes predictably migrate into wounds,[1] their role in the healing process is poorly defined. Antigen-stimulated lymphocytes produce lymphokines, which have been shown to influence *in vitro* fibroblast replication and collagenous protein synthesis.[2,3] Evidence also exists that alterations in host immune response can alter the course of fibroplasia after wounding.[4,5] However, direct *in vivo* proof of lymphocyte participation in wound healing is lacking.[6]

The purpose of this experiment was to elucidate the role of lymphocytes in wound healing by characterizing morphologically the T lymphocyte subpopulations that migrate into wounds at various stages of healing. The aims of this study were: (1) to determine the ratio of T helper/effector:T suppressor/cytotoxic lymphocytes present in wounds, and (2) to study the dynamics of T lymphocyte subsets during wound healing. This was accomplished by using specific monoclonal antibodies to examine T lymphocyte subsets in a rat wound healing model.

Materials and Methods

Male Lewis rats (Harlan Sprague-Dawley, Walkersville, MD), weighing 250–300 g were individually housed at constant temperature (25 ± 1 C) and humidity (40–50%). All rats were fed a complete laboratory chow, Teklad 4% Mouse-Rat Diet (Teklad Test Diets, Madison, WI) and tap water *ad libitum*. The rats were allowed at least 1 week of acclimatization to our laboratory conditions before being used in the experiments.

Under pentobarbital anesthesia (4 mg/kg body weight i.p.) the backs of the rats were shaved and then scrubbed with povidone iodine solution. Using clean conditions, 7-cm dorsal midline wounds were made sharply down to the level of the fascia. At the upper poles of the wound, two sterile, moistened polyvinyl alcohol sponges were placed into subcutaneous pockets. The wounds were then closed with seven interrupted 4-0 stainless steel sutures.

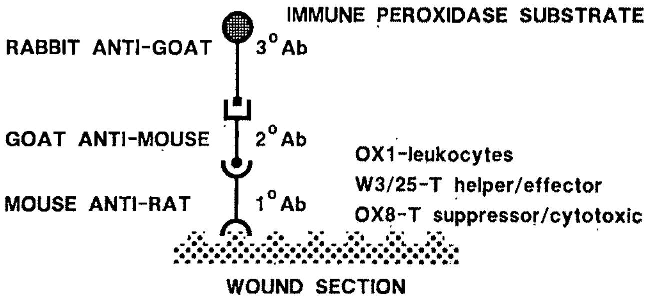

FIG. 1. Diagram of the immunohistochemical staining method used for the identification of antigens on the surface of wound cells by the use of monoclonal antibodies. Three reagents are used: (1) primary antibody, (2) second antibody capable of binding to the first, and (3) biotinylated third antibody. This can then form a biotin–avidin peroxidase complex.

The rats were killed at 5, 7, or 10 days after wounding. A segment of the healing wound was excised and frozen in isopentane cooled to −150 C with liquid nitrogen. Sponge granulomas were cleared of surrounding connective tissue and similarly frozen. Wound blocks and sponges were cut in a cryostat at −20 C. Serial sections were stained using an Avitin–Biotin complex.[7] Briefly, sections were incubated with mouse anti-rat primary monoclonal antibodies (Pel Freez, Rogers, AR) at a 1:50 dilution. The following monoclonal antibodies were used: OX1 against the rat leukocyte common antigen expressed by thymocytes, T and B lymphocytes, and macrophages; W3/25 against the helper/effector T lymphocyte subset; and OX8 against suppressor/cytotoxic T lymphocytes.[8] Sections were then treated with a 1:200 dilution of goat anti-mouse IgG antibody (Calbiochem, San Diego, CA), a 1:800 dilution of tertiary biotinylated rabbit anti-goat IgG antibody (Vector Laboratories, Burlingame, CA), and the Avitin-Biotin immune peroxidase complex (Vector Laboratories, Burlingame, CA).

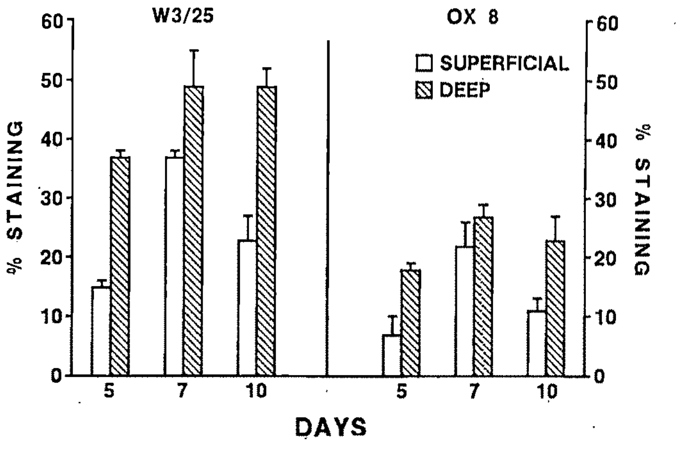

FIG. 2. Mean percentage of mononuclear wound cells stained with W3/25 or OX8 in the superficial and deep portions of the wound.

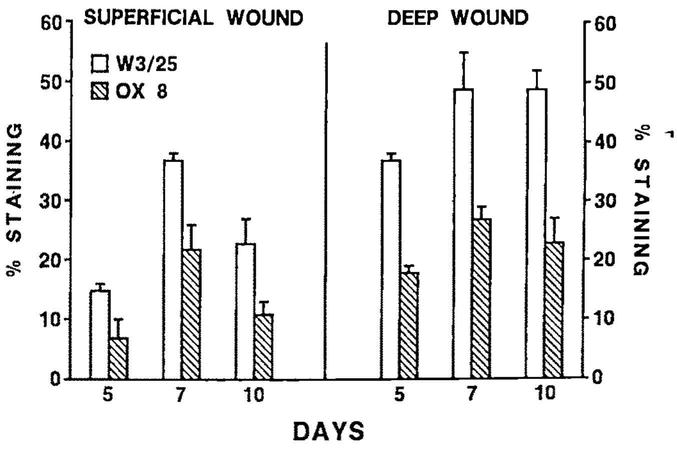

FIG. 3. Mean percentage of mononuclear wound cells stained with W3/25 or OX8 comparing the superficial and deep aspects of the wound.

All incubations were for 30 minutes at room temperature in a humidified atmosphere. Figure 1 is a schematic representation of the staining technique used. Control sections received the same treatment except for the primary monoclonal antibody.

Sections stained with hematoxylin and eosin were studied to identify the wound or the location of cells in the sponge matrix. The mononuclear cell infiltrate of 5-, 7-, and 10-day-old wounds was ranked blindly using the OX1 stains. Cells stained with monoclonal antibody were counted in two areas of the wound: the superficial wound, down to and including the papillary dermis, and the deep wound, the reticular dermis. This division was made arbitrarily as it best reflected the areas of highest cellular infiltration. Cellular staining was quantitated in a blind fashion as follows: the section stained with OX1 that marks all leukocytes was counted. This allowed localization of the mononuclear wound cell populations to be counted in the subsequent serial sections (stained with the W3/25 and OX8 monoclonal antibodies). The exact number of cells counted was dependent on the overall mononuclear cell infiltrate of the wound or sponge. Between 100 and 300 round cells were counted in each area of the wound and the percentage of positivity by stained cells was determined. Likewise, 100–300 round cells were counted in each sponge section and the percentage of positive cells was determined.

Each data point reported in the study represents the mean of six separate wounds. The Mann-Whitney test was used to rank blindly the mononuclear cell infiltrate using the OX1 antibody.

Results

Five-day wounds had a significantly heavier mononuclear cell infiltration than 10-day wounds in the deep

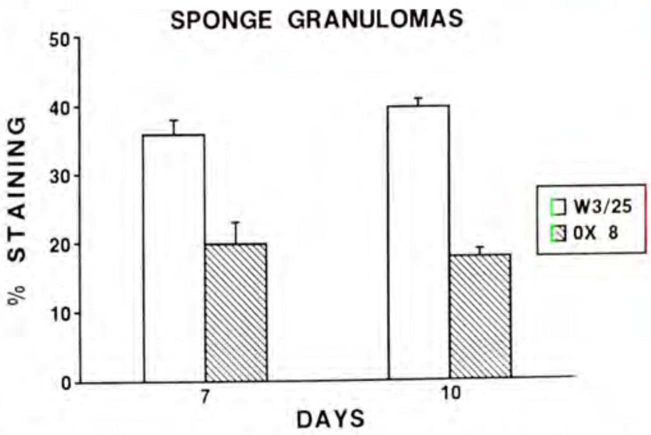

FIG. 5. Mean percentage of mononuclear wound cells stained with W3/25 and OX8 in the sponge matrix at 7 and 10 days.

portion ($p < 0.05$). This was also noted in the superficial section, although not as severe ($p < 0.10$). For 5-, 7-, and 10-day wounds (Fig. 2), lymphocytes labeled with W3/25 predominated over cells bearing the OX8 marker in approximately 2:1 ratios of the mean percentage positive cells in the superficial portions of the wound. There were twice as many W3/25 and OX8 labeled cells in the deep aspect of the wound as in the superficial portion at day 5 (W3/25, 37:15; OX8, 18:7) and day 10 (W3/25, 49:23; OX8 23:11). However, at day 7 there was a peak in W3/25 and OX8 labeled T lymphocytes in the superficial area, whereas the lymphocyte population in the reticular dermis (the deep portion) remained constant (Fig. 3). Figure 4 is an example of a 7-day wound. This is a composite picture showing serial sections of a 7-day healing wound stained with hematoxylin and eosin, monoclonal antibodies and a negative control.

T cells bearing the W3/25 and OX8 markers in the 7- and 10-day sponges were present at the same approximate 2:1 ratio as seen in the wound strips (Fig. 5). In the 5-day sponge, the lymphocytic infiltrate was insufficient to count.

Discussion

This experiment was designed to assess morphologically the migration of T lymphocyte subsets into surgical wounds. We also hoped to demonstrate that lymphocytes migrate to the implanted sponges in the same proportions as they do into the wounds. Were this the case, it would support the hypothesis that cells and fluid obtained from subcutaneously implanted sponges are representative of the cellular infiltrate into the wound itself.

T lymphocyte subsets positive for the W3/25 (helper/effector) and OX8 (suppressor/cytotoxic) markers were found to migrate to the superficial and deep portions of the wound in a 2:1 ratio. These ratios are similar to those reported in rat lymph nodes (1.7–2.3:1),[8,9] but lower than the ratio found in rat peripheral blood lymphocytes (4.2:1).[10] Wound lymphocyte migration is a dynamic process as populations of both W3/25- and OX8-positive T lymphocytes peak in the superficial area of the 7-day-old wound. This is similar to previous data that examined the dynamics of wound lymphocyte infiltration[1]; that study, however, did not study T lymphocyte subpopulations. Lymphocyte subsets infiltrate the implanted sponges in the same 2:1 ratio as seen in the wound, suggesting that the sponge granuloma cellular infiltrate reflects the cellular dynamics of the wound.

The role of lymphocyte participation in the healing process is not clear. Earlier work[6] suggested that wounds of rats depleted of lymphocytes healed dorsal wounds normally. However, we have found that alterations in the host's systemic immune responses influence wound healing. Treatment of rats with immunosuppressive doses of cyclosporin A (which has been shown to decrease the normal T helper/T suppressor ratios)[11] impairs wound healing.[5] Further, adult thymectomy, which abrogates the induction of suppressor T cells, enhances wound healing.[4] *In vitro* evidence suggests that lymphocytes can regulate fibroblast replication and collagen protein synthesis.[2,12] Both stimulated and unstimulated lymphocytes secrete soluble factors, lymphokines, that are reported to either inhibit or enhance fibroplasia.[12] However, the role these factors may play in *in vivo* wound healing remains to be elucidated.

More recently, work from our laboratory has demonstrated that *in vivo* depletion of T lymphocytes impairs wound breaking strength and collagen synthesis in a mouse wound healing model (unpublished data).

The current experiments demonstrate that lymphocytic infiltration of healing wounds is a dynamic process that peaks at 7 days after wounding. Although the morphologic methodology used herein does not allow for direct evaluation of lymphocyte-fibroblast interaction, it may be useful in studying whether the detrimental effect of lympholytic agents such as steroids or chemotherapeutic agents on wound healing is mediated by alterations in wound lymphocyte migration.

Addendum

Since carrying out these studies, a paper has been published using a similar technique to study the appearance of W3/13-positive lymphocytes in healing femoral fractures in rats.[13]

Human Liver Regeneration after Major Hepatic Resection

A Study of Normal Liver and Livers with Chronic Hepatitis and Cirrhosis

NAOFUMI NAGASUE, M.D., HIROFUMI YUKAYA, M.D., YUICHIRO OGAWA, M.D., HITOSHI KOHNO, M.D., and TERUHISA NAKAMURA, M.D.

The regenerative process was evaluated in terms of liver size, function, and histology in 28 adults who had major hepatic resection: hepatocellular carcinoma (HCC) in 21, secondary liver cancer from colorectum in four, carcinoma of the gallbladder in one, Klatskin tumor in one, and Caroli's disease in one. There were 22 men and six women. Ages ranged from 17 to 74 years with a mean age of 56.7. All patients with HCC had underlying liver disease: liver cirrhosis in 14 and chronic hepatitis in seven. Extended right lobectomy was done on 10 patients, right lobectomy on 16 patients, and left lobectomy on two patients. The residual liver size was serially estimated with computed tomography (CT) in 15 patients: six with normal liver, five with chronic hepatitis, and four with cirrhosis. A complete restoration of the residual liver size was found within 3 months in 3 and 6 months, respectively, in two patients with normal livers. The liver was enlarged in all patients with the parenchymal diseases but obviously more slowly compared with normal liver. Liver functions were restored normally within 2–3 weeks in patients with normal livers, but hyperbilirubinemia persisted longer in those with chronic hepatitis and cirrhosis. A continuous rise of bilirubin was an ominous sign of liver failure and subsequent death, which occurred in five patients with cirrhosis. Serum alpha-fetoprotein did not rise in accordance with the regeneration. Histologically, evidence of active regeneration with increased mitotic activity was found at 10 and 35 days in those patients with normal livers. Mitosis was not seen in a specimen taken at 7 days. Enlarged cuboidal hepatocytes and cells with basophilic cytoplasm or two nuclei were observed more or less in all specimens. The livers with cirrhosis or hepatitis also showed histologic evidence of regeneration during the first 2 months but substantially less compared with normal liver, which was well supported by the volumetric study of the liver remnants with CT.

THE LIVER EXHIBITS a remarkable regenerative capacity after major resection provided it is normal. It is commonly assumed that a normal liver tolerates a 70–80% resection safely[1–6] but several authors[7,8] have reported a formidable resection as large as 90% with subsequent regeneration of the liver remnant. On the other hand, it is well known that cirrhotic livers are less able to regenerate and accordingly that major resection is contraindicated in the presence of liver cirrhosis.[3,6] We have recently shown, however, that some of the patients with cirrhosis can tolerate extensive hepatic resection, and therefore that it is wiser to select candidates for major resection from the patients with cirrhosis by quantitative evaluation of hepatic reserve in each case.[9,10]

To date, there have been several clinical works in which the regenerative process of liver remnants was radiologically followed up using liver scan[2,3,6–8,11] or angiography[11–14] or checked by second-look operations.[1,12] These methods, however, do not provide exact estimation of the size of liver remnants. We have investigated the exact volume of the liver after major hepatic resection using computed tomography (CT) in patients with normal liver and livers with chronic hepatitis and cirrhosis. At the same time, the regenerative process was evaluated by conventional function tests and histologic studies.

Materials and Methods

From January 1980 to December 1985, the regenerative process of human liver was evaluated in 28 adult patients who had had major hepatic resection. There were 22 men and six women. Ages ranged from 17 to 74 years with a mean age of 56.7 ± 13.6 years (±SD). Hepatic resections were done for the treatment of hepatocellular carcinoma (HCC) in 21 patients who had either liver cirrhosis (14 patients) or chronic hepatitis (7 patients). Among seven patients with normal liver, four had secondary liver cancer from the colorectum, one

had carcinoma of the gallbladder, and one had cholangiocarcinoma of the liver hilus (Klatskin tumor). The last patient had Caroli's disease of the right hepatic lobe. Extended right lobectomy was done on 10 patients, right lobectomy was done on 16 patients, and left lobectomy was done on two patients.

Measurement of Liver Volume

Volume estimations of the liver remnant were serially performed by CT in 15 patients: six with normal liver, five with chronic hepatitis, and four with liver cirrhosis. As control, the size of normal liver was estimated in six men and six women whose ages ranged from 20 to 70 years. Serial transverse scans of the liver were taken with a GE CT/T 8800 (General Electric Medical Systems, Milwaukee, WI) at 1-cm intervals. All slices of the liver were traced on a tracing paper that was known to produce an exact direct proportion between weight and area. The paper weight of all the hepatic areas was measured with a microestimation balance and the total area of them was gained from the proportional line. The actual volume of the liver was obtained by dividing the data by reduction rate (0.0676).

Liver Function Tests

Conventional liver tests were determined on the first, third, and seventh postoperative days, and at weekly intervals thereafter.

Serum alpha-Fetoprotein Levels

Serum alpha-fetoprotein (AFP) levels were serially estimated in seven patients with normal liver and in five patients with chronic hepatitis up to 15 weeks after hepatic resection. A radioimmunoassay method was used for the measurements.

Histologic Studies

Hepatic specimens were taken by needle biopsy with a Vim-Silverman needle or at the time of relaparotomy or autopsy 7–240 days after operation in 13 patients: five with normal liver, four with chronic hepatitis, and four with liver cirrhosis. The specimens were stained with hematoxylin and eosine, and were evaluated in terms of regeneration of the liver remnant.

Results

Size of the Liver Remnant

The normal liver size was 1086 ± 88 cm^3 in males and 1006 ± 52 cm^3 in females (mean ± SE). Serial changes in the remnant liver size are shown in Figures 1–3. The background of the patients in each category is shown in Table 1. The initial values indicate the sizes of the entire livers with tumors. The size immediately after hepatic resection was calculated by the extent of the resection. Extended right lobectomy was calculated as 80% among

resection, right lobectomy as 60%, and left lobectomy as 40%. Among six patients with normal liver, five had a complete restoration of liver volume within 7 months (Fig. 1 and Fig. 4). Three of them had a larger liver than normal within 3 months. In an oldest patient (Case 2) who had carcinomatous peritonitis occurring soon after operation, the liver regeneration was substantially insufficient. In the presence of chronic hepatitis, two patients had a rapid regeneration of the liver remnant (Fig. 2 and Fig. 5). The liver grew more gradually in two patients and size never exceeded the normal liver volume up to 9–12 months after operation. In the youngest patient, the liver remnant was larger than normal only 3 weeks after operation but it regressed 3 months later probably due to extensive intra-arterial chemotherapy with 5-fluorouracil, doxorubicin, and mitomycin C. Among four patients with liver cirrhosis, the size of liver remnants returned nearly to normal 9–12 months after operation in two patients. It was restored to 879 cm^3 at 6 months in one patient (Case 3) (Fig. 3 and Fig. 6). One patient (Case 2) had gradual liver growth after extended right lobectomy for 4 months but no enlargement was found thereafter. The liver size in this patient remains at approximately 500 cm^3 but he has been leading a normal life.

Liver Functions

Aspartate aminotransferase (AST) activities were substantially elevated in all patients on the first postoperative day but returned to the preoperative levels within 2 weeks in most patients. The peak of the enzymatic activity was significantly lower in the patients with cirrhosis than in the noncirrhotic patients (Fig. 7). Serum bilirubin levels rose immediately after operation in most patients. They returned to normal within 2 weeks in pa-

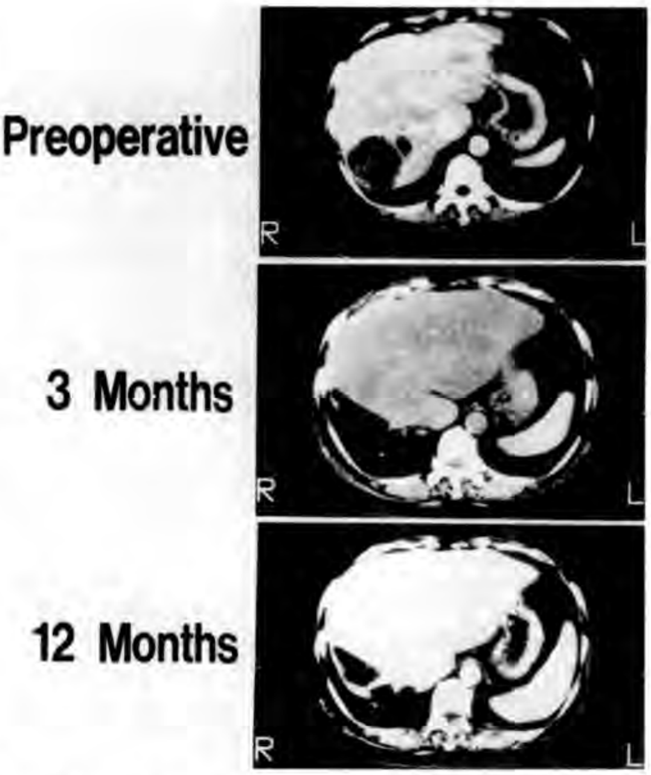

FIG. 4. Serial CT scans after right lobectomy in a patient with normal liver (Case 3).

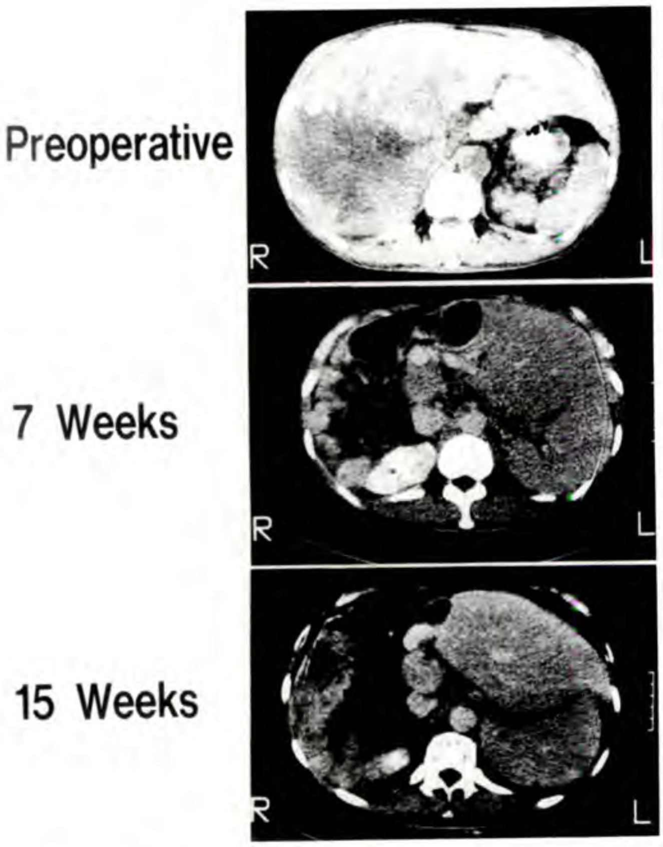

FIG. 5. Serial CT scans after extended right lobectomy in a patient with chronic hepatitis (Case 2).

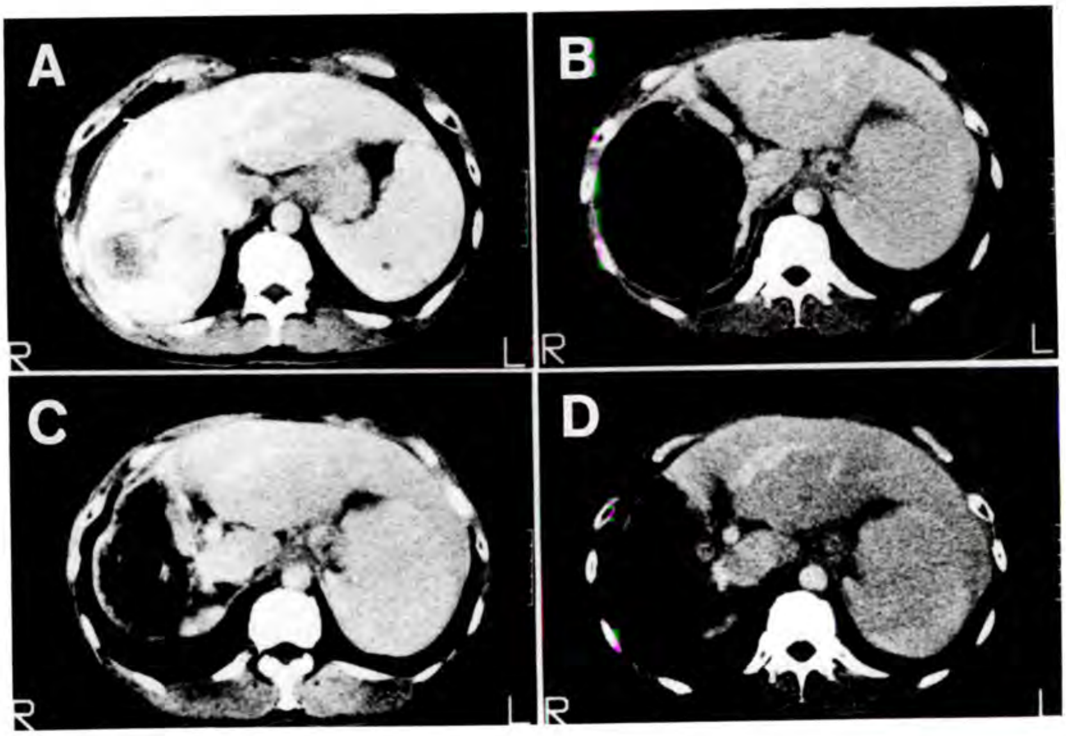
tients with normal livers but this retarded in the patients with chronic hepatitis. This tendency was more intense in the patients with cirrhosis and the five patients who died of liver failure had a progressive elevation of bilirubin levels (Fig. 8). Serum protein levels rarely fell below 6.0 g/100 mL in those patients with normal livers. On the contrary, patients with cirrhosis showed a profound drop despite extensive substitution, and this trend was most severe in the patients who died of liver failure (Fig. 9). Changes in total cholesterol levels were similar to those in total protein (Fig. 10).

Serum AFP

Serum AFP concentrations were fluctuated within normal ranges in all patients who had normal livers. In patients with chronic hepatitis, AFP was never elevated in accordance with regeneration of the liver remnant. One exception was a patient in whom cholestatic hepatitis occurred 5 weeks after operation. Serum AFP was transiently elevated during the recovery phase of the hepatitis in this patient (Fig. 11).

Histologic Findings of Liver Remnants

Normal liver. The cytoplasm of hepatocytes at the periportal zone became basophilic, and cellular enlargement and sinusoidal dilatation of slight degree were observed at 7 days. Mitotic figures were not seen although



FIGS. 6A–D. Serial CT scans after right lobectomy in a patient with liver cirrhosis (Case 4). *A.* Preoperative CT scan. *B.* 1.5 months. *C.* 6 months. *D.* 12 months.

binuclear cells were sporadically observed. Steatosis of moderate degree was found. The number of basophilic hepatocytes increased at 10 days. There were many enlarged cuboidal hepatocytes. Cells with mitosis and two nuclei were frequently seen. The sinusoids were dilated but liver steatosis was very slight (Fig. 12). Similar findings were observed in the specimen taken 35 days after operation. Almost normal histologic configurations were found in the specimens obtained 4 and 5 months after operation.

Chronic hepatitis. In the liver taken 30 days after extended right lobectomy, there were a few hepatocytes with basophilic cytoplasm and enlarged cuboidal cells. Binuclear cells were remarkably found but there were no mitoses. Neither sinusoidal dilatation nor liver steatosis was observed (Fig. 13). These findings were more slight in the specimens taken at 60 days, 7 months, and 8 months.

Liver cirrhosis. In the liver taken 13 days after right lobectomy, more basophilic liver cells were found compared with before operation. Although binuclear cells were sporadically seen, there were no hepatocytes with mitosis. Few enlarged cuboidal cells were noted. Steatosis or sinusoidal dilatation was not remarkable. Similar findings were observed in the specimen taken at 33 days. In a patient who died of liver failure 15 days after operation, necrosis of centrizonal hepatocytes was diffusely found. No regenerative reaction was observed. In another patient who died of chronic liver failure at 56 days, liver cells were preserved rather well. There were many sludges of bile pigments in the bile ductules. Few findings suggesting liver regeneration were observed (Fig. 14).

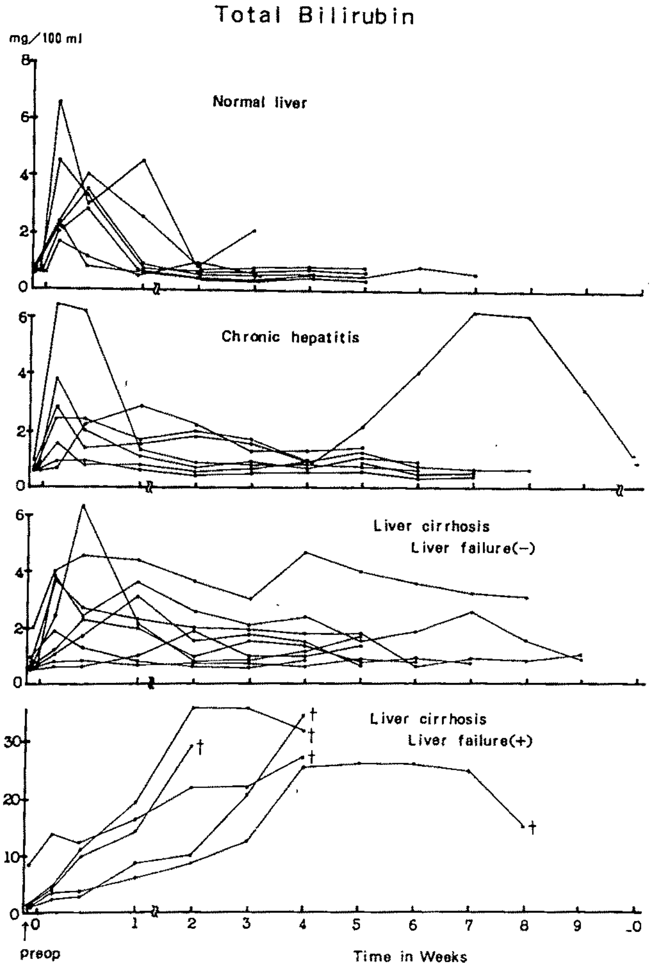

FIG. 8. Changes in serum bilirubin levels after major hepatic resection.

Discussion

Details on human liver regeneration are difficult to obtain unlike experimental animals for apparent reasons. Pack et al.[1] in 1962, confirmed a rapid regeneration of the residual liver during relaparotomy in four patients who had undergone major hepatectomy for the

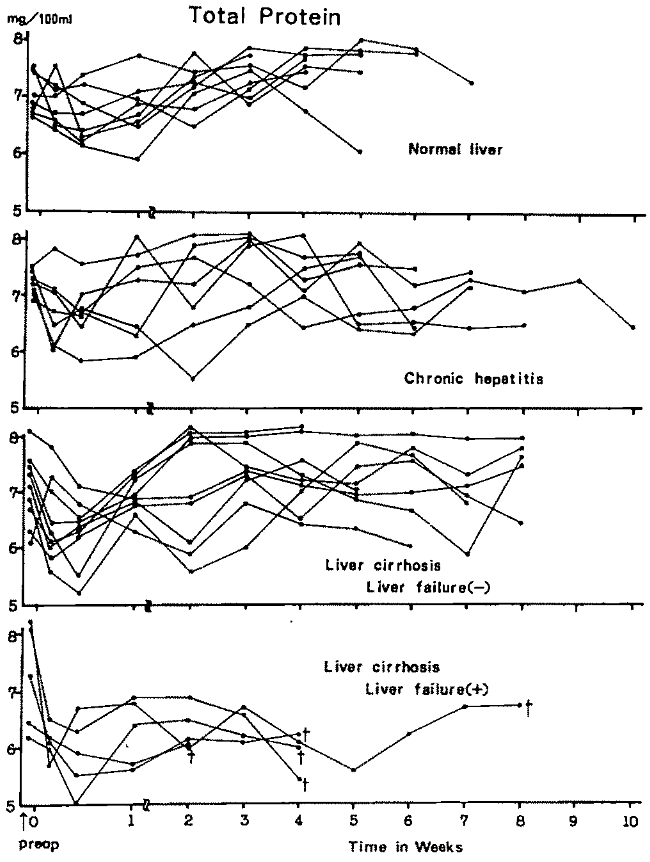

FIG. 9. Changes in serum protein levels after major hepatic resection.

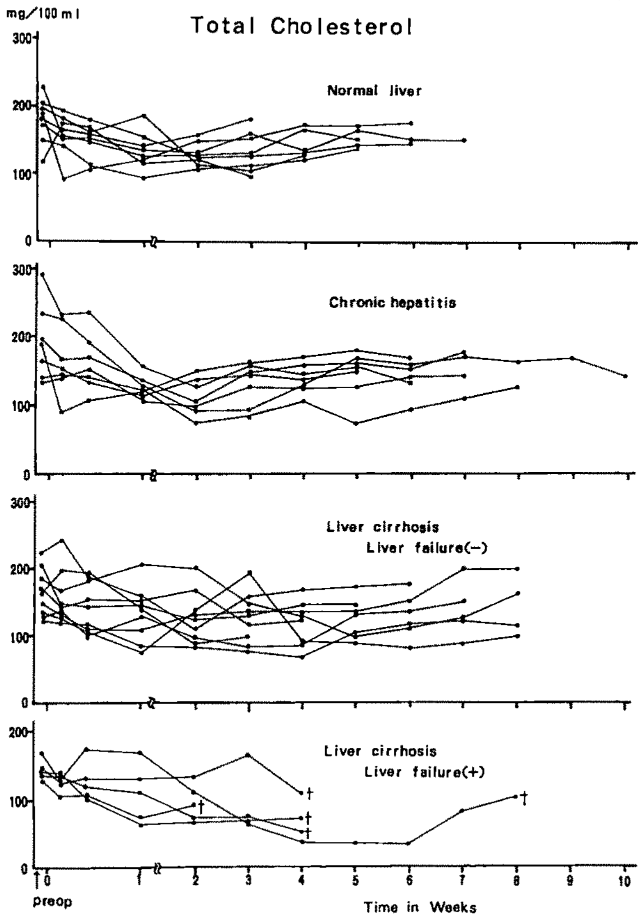

FIG. 10. Changes in serum cholesterol levels after major hepatic resection.

treatment of cancer. Thereafter, several investigations on regeneration of normal human liver were reported with the aids of liver scan[2,3,6–8,11] and angiography.[11–14] The general conclusion from those studies was that a normal liver regains its original size within 6 months after extensive hepatic resection.[2,4,7,12]

In the current study using CT, three patients with normal liver showed a complete restoration of the residual liver size within 3 months. Slower and incomplete regeneration was found in only one patient who had carcinomatous peritonitis immediately after the operation. In the patients with chronic hepatitis and liver cirrhosis, the remnant liver was enlarged but obviously more slowly compared with normal liver. Among four patients with chronic hepatitis, only one had a rapid regeneration. Three patients had on-going regeneration 9–15 months after operation. Two patients with cirrhosis had a nearly normal liver volume at 9 and 12 months after operation, respectively. In one cirrhotic patient with extended right lobectomy, the residual liver has grown up to only one half of the normal size but he has been leading a normal life.

Thus, a normal liver seems to regenerate much faster than previously assumed. Cirrhotic livers or livers with chronic hepatitis, on the other hand, enlarge more

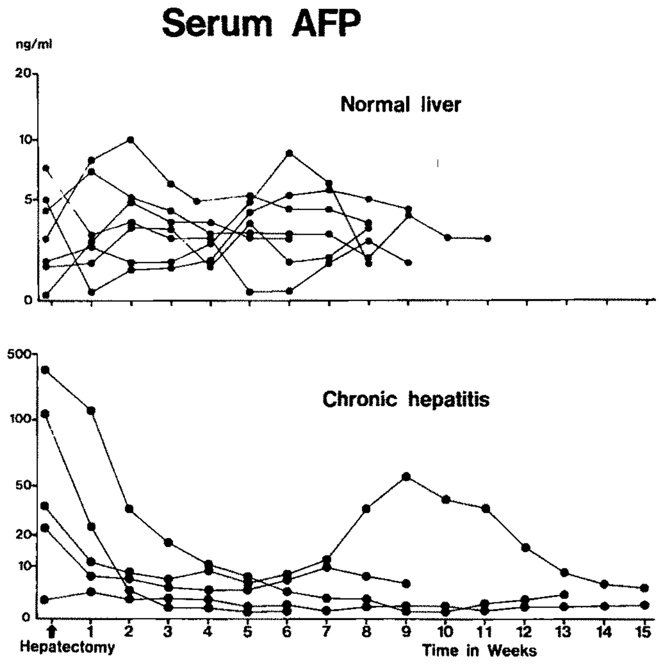

FIG. 11. Changes in serum AFP levels after major hepatic resection (normal range: less than 20 ng/mL).

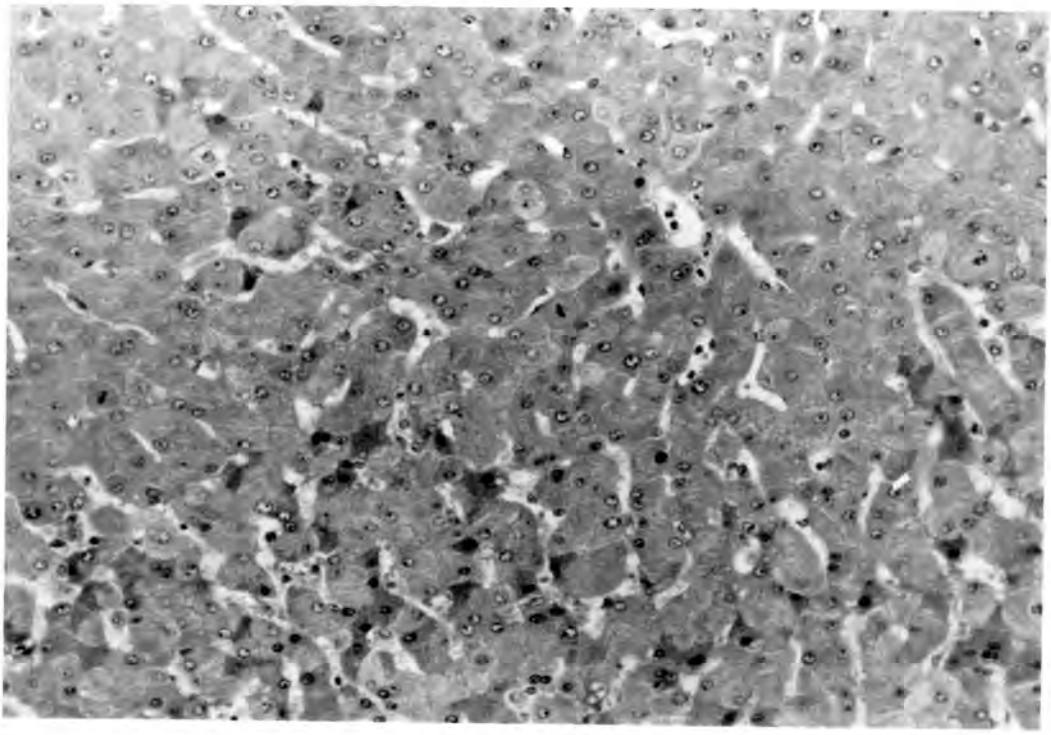

FIG. 12. Histology of the residual liver taken 10 days after right lobectomy in a patient with normal liver (hematoxylin and eosin, original magnification ×50).

slowly, but complete restoration of the residual liver is possible in some patients with these parenchymal diseases. Lin and his associates[3,6] claim that a cirrhotic liver cannot regenerate and, therefore, that major hepatic resection is contraindicated in the presence of cirrhosis of the liver. Our current study casts a question to this. Probably the prognosis of patients with cirrhosis who have major hepatic resection depends on the extent of the cirrhosis. In fact, Kohno et al.[15] have found that the prognosis of dogs with experimentally induced cirrhosis was well reflected by the extent of the cirrhosis. The "all or nothing theory" that cirrhotic livers do not tolerate a

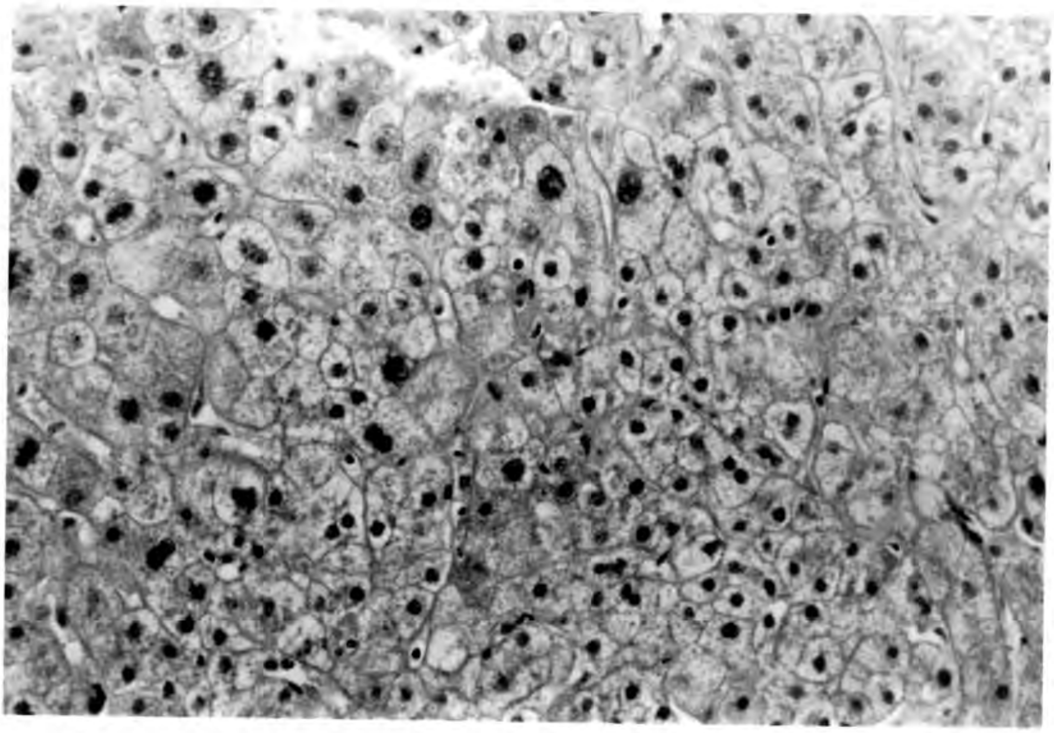

FIG. 13. Histology of the residual liver taken 30 days after extended right lobectomy in a patient with chronic hepatitis (hematoxylin and eosin, original magnification ×297).

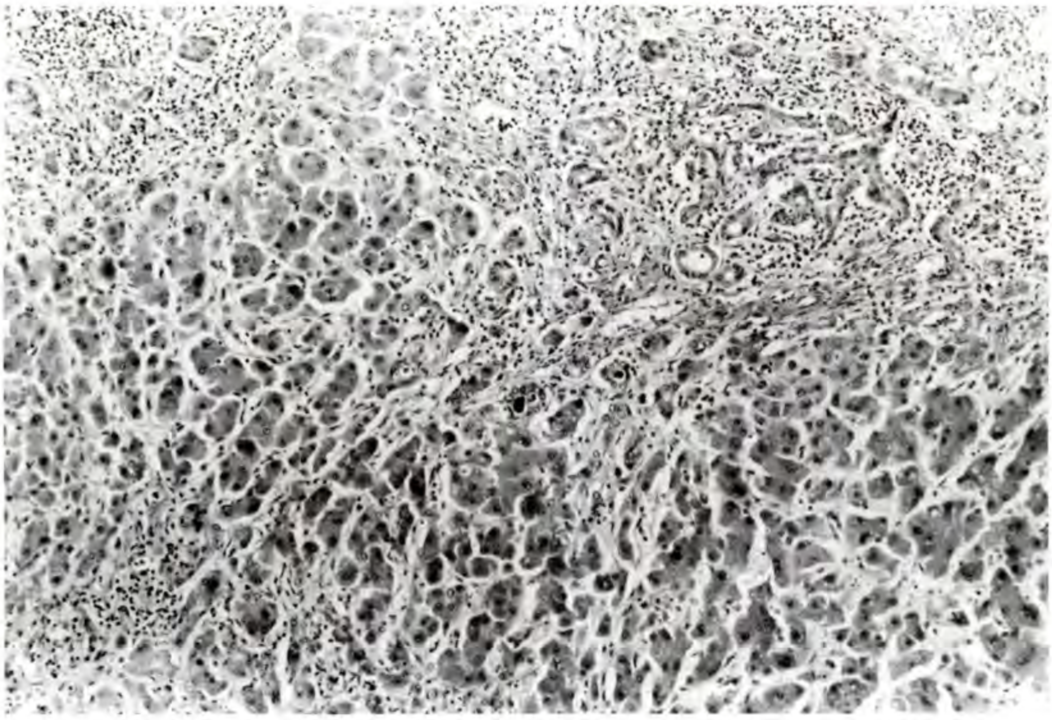

FIG. 14. Histology of the residual liver at autopsy 56 days after right lobectomy in a patient with liver cirrhosis who died of hepatic failure (hematoxylin and eosin, original magnification ×25).

major resection seems to be invalid. We should select candidates for such resections by a quantitative, not qualitative, evaluation, although it is difficult how to do it.[9,10]

Postoperative liver functions were restored almost normally within 2–3 weeks in patients with normal livers. This correlates with the previous results.[2,3,5,16–18] However, hyperbilirubinemia of slight degree persisted longer in the patients with parenchymal disease. A steady rise of serum bilirubin was an ominous sign of hepatic failure in the patients with cirrhosis. None of the patients with chronic hepatitis, either active or inactive, had such a continuous elevation of bilirubin and subsequent hepatic failure.

It is well known that the peak of mitosis of hepatocytes occurs 24–28 hours in rats[19] and 4 days in dogs[20] after 70% hepatectomy. No data are available on this subject in human liver. Vajrabukka et al.[5] found histologic evidence of regenerative hyperplasia with increased mitotic activity within 3 days after partial hepatectomy. Lin et al.[6] also histologically observed regeneration of the normal residual liver 5–27 days after operation. In our patients with normal liver, mitoses were found at 10 and 35 days but not at 7 days. Enlarged cuboidal hepatocytes, cells with basophilic cytoplasm or two nuclei, and liver steatosis were observed more or less in all these specimens. The liver remnant was morphologically normal 4–5 months after operation. In light of this and previous studies,[5,6] it is likely that normal human liver starts to regenerate soon after partial hepatectomy and cellular proliferation continues for several weeks thereafter. The liver with cirrhosis or hepatitis also showed histologic evidence of regeneration but obviously less compared with normal liver, which was well supported by the volumetric study of liver remnants with CT.

Serum AFP was not a reliable indicator for liver regeneration after partial hepatectomy as previously suggested by Alpert and Feller[21] and ourselves.[22] Serum AFP was never elevated during the period of active regeneration of the liver remnant in patients with normal livers or chronic hepatitis. It rose transiently during the recovery phase of postoperative hepatitis in one patient who had chronic hepatitis initially and had undergone extended right lobectomy. Therefore, we are reluctant to assume that the elevation of serum AFP that is occasionally seen in chronic liver disease is reflected by regeneration of the liver.

Regional Therapy in the Management of Intrahepatic Recurrence after Surgery for Hepatoma

YO SASAKI, M.D., SHINGI IMAOKA, M.D., MAKOTO FUJITA, M.D.,* YASUO MIYOSHI, M.D., HIROAKI OHIGASHI, M.D., OSAMU ISHIKAWA, M.D., HIROSHI FURUKAWA, M.D., HIROKI KOYAMA, M.D., TAKESHI IWANAGA, M.D., HIROSHI KASUGAI, M.D.,† and JUNNOSUKE KOJIMA, M.D.†

The significance of regional therapy against the intrahepatic recurrence for hepatocellular carcinoma (HCC) was evaluated. During the past 6 years, 101 patients who had radical operations for HCC (liver cirrhosis, 75%; chronic hepatitis, 22%) were followed. Forty-seven patients (47%) had recurrences; the liver was the site of first recurrence in 43 patients and distant site recurrence in four patients. In the patients where the liver was the recurrent site, 33 patients (77%) received regional therapies for an aggregate total of 60 times. Transcatheter arterial chemoembolization was chosen as the first preferred therapy against recurrence in the liver in 30 of 33 patients (91%). Postrecurrence survival of the patients treated with regional therapy was significantly better than disease-free survival ($p < 0.001$). Disease-free survival after surgery, postrecurrence survival, and postsurgery survival were compared in the patients treated with regional therapy and untreated patients. Fifty per cent survival after recurrence of the treated patients was 27 months, and that of the untreated patients was 3 months. Postrecurrence survival ($p < 0.001$) and postsurgery survival ($p < 0.01$) of the treated patients were significantly better than those of the untreated patients. To obtain successful long-term survival after surgery for the cirrhotic patients with HCC, it is necessary to repeat active regional therapies against the recurrent liver.

THE PATIENTS WHO HAD hepatocellular carcinoma (HCC) with liver cirrhosis were excluded from indications for hepatic resection in Western countries because of poor prognosis.[1,2] Since, however, HCC in Asian countries, including Japan, is associated with cirrhosis in high frequency,[3,4] the cirrhotic patients with HCC cannot be eliminated from the subjects of the treatment for clinicians who practice in areas where prevalence of the disease is high. In recent years, the remarkable progress in imaging modalities, such as ultrasonography (US), computed tomography (CT), and the monitoring of serum α-fetoprotein (AFP) levels in high-risk patients, has made it possible to detect small HCC at an early stage. Consequently, the surgeons have been able to resect HCC successfully at a relatively early stage in some patients. Moreover, the improvement of the assessment of resectability,[5,6] the concept of limited operation,[7] and the subsegmental or partial resection using intraoperative US[8,9] have produced high resectability and low operative mortality rates. However, the long-term survivals after surgery reported by the surgeons in the Asian countries are not yet satisfactory. Tsuzuki et al.[10] reported that the 3-year actual survival rate was 31%, Okamoto et al.[11] reported that the 3- and 5-year survival rates were 26.7% and 13.3%, respectively, and the recent report by Lee et al.[12] showed a 28% survival rate for 1400 days. One reason for these poor cure rates is believed to be related to the high recurrence rate in the liver remnant because the cirrhotic liver limits the extent of the hepatic resection.

During the past 6 years, we have carefully followed up on the patients who had surgical resection for HCC at the Center for Adult Diseases, Osaka, Japan. When recurrences were recognized in the liver, the active regional therapies were applied. In this study, the significance of the regional therapy against the intrahepatic recurrences for HCC is evaluated.

Patients and Methods

During the past 6 years ending in June 1986, 114 patients with HCC had radical hepatic resection at this center. Of the 114 patients, 13 had either operative or in-hospital death; therefore, the remaining 101 patients (89%) were studied. Surgery was defined to be radical in cases where all gross disease was removed, including a

disease-free resection margin. The 101 patients included 82 men (81%) and 19 women (19%), ranging in age from 35 to 75 years (mean: 58 years). Seventy-six patients (75%) had cirrhosis, 22 patients (22%) had chronic hepatitis, and three patients (3%) had normal parenchyma. Thirty-eight patients (38%) had partial hepatic resection, 26 patients (26%) had hepatic subsegmentectomy,[13] 24 patients (23%) had hepatic segmentectomy, and 13 patients (13%) had hepatic lobectomy or extended hepatic lobectomy. After resection, the patients were followed up every 1-3 months. AFP assays, liver function tests, liver US, and chest x-ray were routinely performed. When recurrences were suspected, the patients received liver CT and were readmitted to the hospital for hepatic angiography.

Statistical Analysis

Cumulative survival rates and curves were calculated using the Kaplan-Meier method. The generalized Wilcoxon test was used to compare the survival curves. The p values less than 0.05 were considered to be statistically significant.

Results

Recurrence and Survival

By the end of September 1986, 47 of 101 patients (47%) had recurrences. Twenty-nine patients with recurrence (62%) had recurrences within 1 year after surgery, nine patients (19%) had recurrence from 1 to 2 years after surgery, seven patients (15%) had recurrence from 2 to 3 years after surgery, and the remaining two patients had recurrence more than 3 years after surgery. Of the 47 patients, the liver was the site of first recurrence in 43 patients (91%), and four (4%) were found in distant sites. At this time, 69 patients (68%) were alive and 32 patients (32%) were dead. The 1-, 3-, and 5-year disease-free survival rates of the 101 patients were 70%, 36%, and 30%, respectively, and the 1-, 3-, and 5-year survival rates of these were 87%, 64%, and 40%, respectively (Fig. 1).

Tumor Size, Extent of Resection, and Disease-free Survival

To examine the influence of tumor size and the extent of resection on the recurrence, disease-free survivals after surgery with respect to these factors were calculated (Fig. 2 and Fig. 3). A statistically significant difference was found among the groups with the tumor size below 2 cm and the group with the tumor size exceeding 10 cm ($p < 0.05$). The 2-year disease-free survival rate of the group with the tumor size below 2 cm was significantly better than the other groups. There were no significant differences among the groups with the tumor size exceeding 2 cm (Fig. 2). On the other hand, the extent of resection did not influence disease-free survival (Fig. 3).

Regional Therapy against the Intrahepatic Recurrence

In the 43 patients where the liver was the site of first recurrence, 33 patients (77%) received the regional therapies (Fig. 4 and Fig. 5) and the remaining 10 patients (23%) did not. Interventional angiographic technique was chosen as the first therapy against the recurrent disease in 30 of 33 patients (91%). As one of the transcatheter procedures, chemoembolization, *i.e.*, the combination of intra-arterial infusion of a chemotherapeutic agent and arterial embolization, was mainly performed under the following regimens: (1) by absorbable gelatin sponge cubes (Gelfoam®; Upjohn Company, Kalamazoo, MI) after arterial infusion of 40–60 mg of adriamycin (ADM); (2) after arterial infusion of 10–20 ml of ethiodized oil (Ethiodol®; Savage Laboratories, Melville, NY, Lipiodol®; Laboratoire Guerbet, Aulnay-sous-Bois, France) containing 40–60 mg of ADM; and (3) chemoembolization using a combination of 10–20 ml of ethiodized oil, 2 mg/kg of body weight of cisplatin (CDDP), and Gelfoam.[14] When the tumor emboli were recognized in the trunk or the first branch of the portal vein on the hepatic portogram, embolization with Gelfoam was not performed, and the anticancer agent alone, or the anticancer agent plus ethiodized oil, was injected through the hepatic artery. One patient had hepatic resection as a first therapy against the recurrence. Two patients had cannulation and/or ligation of the hepatic artery through surgery because the transcatheter approach was impossible. They received intra-arterial chemotherapy or chemoembolization *via* the cannulated tube. Subsequent to first therapy against recurrence, the patients were followed up again. When relapse was recognized, the regional therapies were repeated. As a rule, when the previous therapy was considered to be effective, the same regimen was adopted. If the previous therapy seemed to be ineffective or when the same therapy was impossible to repeat, one of the other therapies was chosen. One patient received the regional therapies five times after recurrence, two patients received them four times, nine patients received them three times, 15 patients received them twice, and the remaining patients received them once (Fig. 4 and Fig. 5).

Comparison between Disease-free Interval and Postrecurrence Interval

Disease-free interval and postrecurrence interval were compared in the 33 patients who received the regional therapy against the intrahepatic recurrence (Fig. 5). In 17 patients who had already died, the median value of the disease-free interval was 13 months and that of the postrecurrence interval was 19 months. Thirteen patients (76%) had longer postrecurrence intervals than disease-free intervals. Moreover, in the 16 patients who are still living, the postrecurrence intervals of the 11 patients (69%) have already been longer than their disease-free intervals. Survival after recurrence and disease-free survival after surgery of these 33 patients were calculated (Fig. 6). The 50% survival rate of the former group of patients was 27 months and that of the latter group was 9 months. The difference between these figures was statistically significant ($p < 0.001$).

Comparison of Survivals between the Patients with and without Regional Therapies

Disease-free survival after surgery, survival after recurrence, and survival after surgery were compared between 33 patients who received the regional therapies and 10 patients who did not (Fig. 7A–C). There was no statistically significant difference between the two groups regarding the disease-free survival (Fig. 7A). The 50% survival after recurrence in the patients receiving regional therapies was 27 months, and the 1-, 2-, 3-, and 4-year postrecurrence survival rates were 84%, 53%, 25%, and 25%, respectively. On the other hand, survival of the patients without the regional therapies was 3 months, and the longest survival was 9 months after recurrence. The difference between these figures was statistically significant ($p < 0.001$) (Fig. 7B). The 50% survival after surgery of the treated patients was 47 months, and the 1-, 3-, and 5-year survival rates were 87%, 70%, and 30%, respectively, whereas that of the untreated patients was 15 months with the 1-, 3-, and 5-year rates of 60%, 10%, and 10%, respectively. The difference between these two figures was also statistically significant ($p < 0.01$) (Fig. 7C).

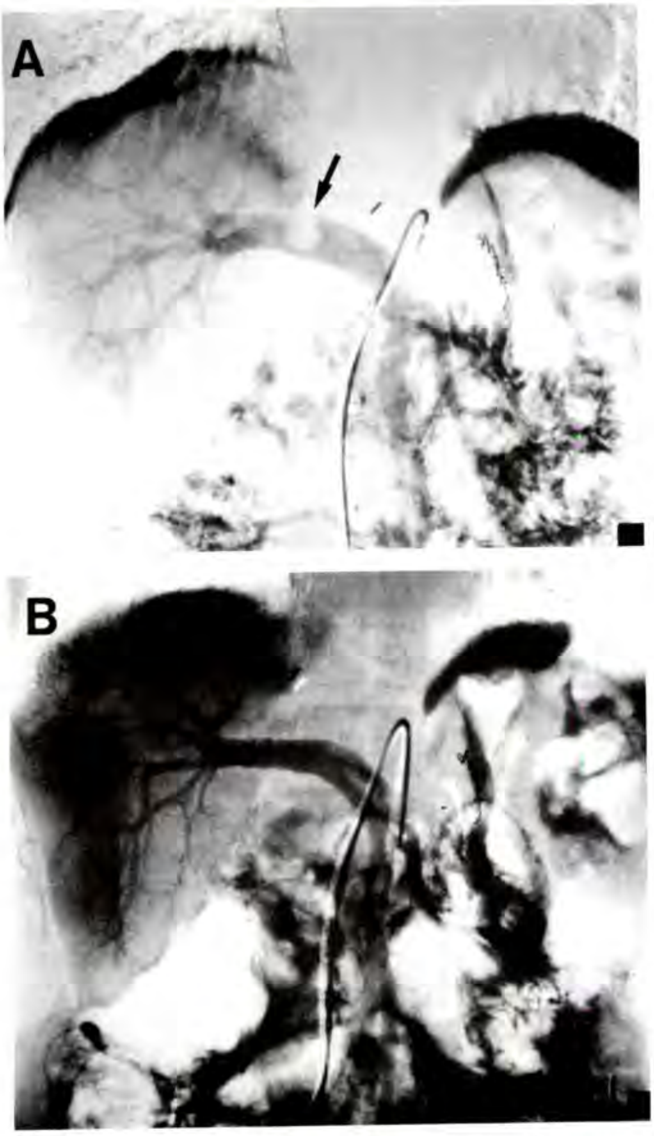
Comparison of Postrecurrence Survivals among the Patients Treated by Three Chemoembolization Regimens

Survivals after recurrence were compared among the three groups treated by interventional angiographic technique as the first regional therapy after recurrence (Fig. 8). There were no statistically significant differences among these figures, but the 1-year survival rate of the group treated by Ethiodol, CDDP, and Gelfoam was significantly better than that of the group treated by Ethiodol, ADM, and Gelfoam ($p < 0.05$).

Case Reports

Case 1

This 59-year-old male patient had partial hepatic resection of anterior and medial segment under the diagnosis of HCC in June 1981. The main tumor was 6.0 × 5.0 cm and was surrounded with many daughter nodules in the resected specimen. In January 1982, recurrent lesions were found in the liver remnant through US and hepatic angiography. The patient received chemoembolization with Gelfoam containing 50 mg of ADM after the angiography. Afterwards, the same therapy was repeated twice for the relapse. In July 1984, the celiac angiogram showed the complete obstruction of the common hepatic artery, but the superior mesenteric arteriogram showed collaterals from the pancreaticoduodenal arcades (PDA) and gastroduodenal artery (GDA) to the proper hepatic artery. He had an infusion of 50 mg of ADM alone from the catheter placed in the inferior pancreaticoduodenal artery due to the failure of superselective catheterization. In



FIGS. 9A and B. Hepatic portogram of Case 2. *A.* Hepatic portogram before the third operation. Arrow points to the defect of the portal trunk by tumor embolus. *B.* Hepatic portogram after the third operation. No tumor embolus is observed.

October 1984, the cannulation into the proper hepatic artery was performed surgically. Three times the patient received an intra-arterial infusion of ADM concomitantly with angiotensin II.[15] However, because the extravasation of the drug by the penetration of the tip of the catheter occurred, the treatment had to be discontinued. In September 1985, the superior mesenteric angiogram showed the collaterals from PDA, GDA, and epicholedochal arterial plexuses into the liver. At this time, as the tip of the catheter was advanced to GDA through PDA, the chemoembolization using Ethiodol, CDDP, and Gelfoam was done. Regardless of the development of intrahepatic recurrences 7 months after hepatic resection, the patient is still alive more than 5 years after surgery.

Case 2

This 69-year-old male patient, who had HCC with liver cirrhosis, had partial resection of anterior segment in September 1982. In June 1983, as a single tumor was found in the lateral segment of the liver, he had lateral segmentectomy. Moreover, in March 1984, the existence of a tumor embolus in the trunk and the left branch of the portal vein was detected through US. Hepatic portogram demonstrated a round defect of contrast medium in the portal trunk and the disappearance of the left portal vein (Fig. 9A). The medial segmentectomy and embolectomy in the portal trunk were performed in April 1984. Hepatic portogram taken after surgery exhibits removal of the tumor embolus in the portal trunk (Fig. 9B). In May 1986, a small focus was discovered in the posterior segment, and he received the chemoembolization using Ethiodol, CDDP, and Gelfoam. The patient is still alive more than 4 years after his first surgery.

Discussion

Lee et al.[12] reported that the tumor size did not affect the patients' survival but an adequate margin of the tumor specimen prolonged the survival significantly longer than that of inadequate margins. However, even the 4-year survival rate of the adequate margin group was under 40%. In our study, the size of the tumor, when over 2 cm in diameter, and the extent of hepatic resection did not affect the incidence of the patients' recurrence (Fig. 2 and Fig. 3). These findings indicate that it is nearly impossible to control the cancerous lesion of the patients with cirrhosis completely by hepatic resection alone. As an explanation, it is conceivable that the microscopic intrahepatic metastasis has already occurred in an earlier stage or the cirrhotic liver has multicentric metachronous or unnoticed synchronous carcinogenesis. Whether or not, at the current stage, slightly wider and more extensive resection within the limitation of the reserve capacity of the cirrhotic liver does not seem to avoid the occurrence of intrahepatic recurrence in any significant frequency.

Therefore, to obtain a successful long-term survival after surgery for cirrhotic patients with HCC, it is necessary to detect earlier intrahepatic recurrences using close follow-ups and to repeat active regional therapies against the recurrent lesions. Lee et al.[12] reported that the survival of the patients who had more than two operations was significantly longer than that of the patients who had only a single operation. Nagasue et al.[16] reported recently that a second hepatic resection is a possible and meaningful method for patients with recurrent HCC in the liver remnant. Their findings also suggest effectiveness of the regional therapy for recurrent liver. In the current study, only one patient had resection three times (Case 2). Practically speaking, the number of patients for whom the second hepatic resection in the treatment of recurrent HCC is possible are few because of the multiple recurrent foci, progressive liver dysfunction, and the patients' rejection. We mainly chose the transcatheter arterial chemoembolization as the first-choice therapy for most of the patients with recurrence. Recently, arterial embolization and chemoembolization have been considered to be useful therapeutic procedures for HCC. Yamada et al.[17] reported the treatment of 120 patients with unresectable HCC by arterial embolization with Gelfoam. The 1-, 2-, and 3-year cumulative survival rates were 44%, 29%, and 15%, respectively. More recently, many articles from Japan have recommended chemoembolization using ethiodized oil, a chemotherapeutic agent, and Gelfoam.[18,19] Results using these methods were superior to embolization with Gelfoam alone. A method using ethiodized oil, CDDP, and Gelfoam was developed by us as one of the regimens of chemoembolization, and its efficacy has been reported previously.[14] These angiographic techniques can be performed more safely and easily than surgical resection for patients with cirrhosis.

By repeating the regional therapies against the intrahepatic recurrences, many of our patients had longer postrecurrence intervals than disease-free intervals. Consequently, the 5-year cumulative survival rate of all patients who had the radical operation was 40%. This survival rate is better than any other reported by surgeons in Asian countries. Our results obtained by regional therapies for the recurrent liver may raise a question as to whether surgery is the first-choice therapy for the cirrhotic patients with HCC. Surgery is generally considered to be superior to any other therapeutic procedures, and we have observed some cirrhotic patients with HCC who have survived over 5 years without recurrence through surgical procedures alone. To settle this problem, a control study will be necessary between surgery alone and chemoembolization alone in patients at resectable stages. As long as adequate survival data of patients treated by chemoembolization do not confirm efficacy to establish it as an alternative to surgery, we believe hepatic resection should be chosen as a first-choice therapy.

We also believe that prevention of cancer recurrence is more important and realistic than treatment after recurrence. However, genuine value of postoperative adjuvant chemotherapy has not yet been enlightened. Since the reserve capacity and the regeneration ability of the cirrhotic liver are remarkably poor, the use of cytotoxic drugs immediately after hepatic resection may delay the regeneration of residual liver and advance the liver dysfunction.[20,21] Therefore, currently we consider that repeating active regional treatments against intrahepatic recurrences after hepatic resection constitutes the best means for the management of HCC coexisting cirrhosis to gain a long-term survival after surgery.

Emergency Portacaval Shunt for Variceal Hemorrhage

A Prospective Study

JEAN-PIERRE VILLENEUVE, M.D., GILLES POMIER-LAYRARGUES, M.D., LESTER DUGUAY, M.D.,
RÉAL LAPOINTE, M.D., SERGE TANGUAY, M.D., DENIS MARLEAU, M.D., BERNARD WILLEMS, M.D.,
P.-MICHEL HUET, M.D., CLAIRE INFANTE-RIVARD, M.D., and PIERRE LAVOIE, M.D.

Emergency portacaval shunt for variceal bleeding is associated with a high operative mortality, particularly if used as a last resort. Because of this, a strong case has been made against emergency shunt. This report describes an experience with emergency portacaval shunt for the treatment of variceal bleeding when used systematically after hemodynamic stabilization and control of the bleeding episode with balloon tamponade, if necessary, in patients with mild or moderate liver disease. The population studied comprised 62 consecutive patients who rebled from varices while participating in a controlled trial of propranolol for the prevention of rebleeding. Of the 62 patients, nine died of massive hemorrhage and 53 survived the hemorrhage. Of the 53 survivors, 11 had severe liver disease and were not considered for shunt surgery. Of the remaining 42 patients with mild or moderate liver disease, 36 had emergency central portacaval shunt. The interval between endoscopic diagnosis of variceal bleeding and surgery averaged 19 ± 3 hours (mean ± SE). The operative mortality rate, defined as in-hospital mortality, was 19%. One- and 2-year survival rates were 78% and 71%, respectively. The incidence of postoperative hepatic encephalopathy was 36%; all patients responded favorably to protein restriction and lactulose. Thus, under specific conditions, emergency portacaval shunt results in an acceptable long-term survival rate. In patients with mild or moderate liver disease, emergency portacaval shunt should be considered when other forms of treatment for the prevention of variceal rebleeding have failed.

From the Liver Unit and Departments of Medicine, Surgery, and Epidemiology, Hôpital Saint-Luc and Université de Montréal, Montreal, Canada

HEMORRHAGE FROM ESOPHAGEAL VARICES is a life-threatening complication of portal hypertension in patients with cirrhosis. Among patients admitted for variceal hemorrhage, 80% will rebleed and 60% will die within 1 year.[1] In addition, the risk of rebleeding and death is much higher within the days and weeks after the initial hemorrhage, and decreases thereafter.[1,2] Thus, any substantial improvement in survival must rely on maneuvers that can be used early after the initial bleeding to prevent recurrences.

Four randomized trials of therapeutic portacaval shunt have shown no significant improvement in survival with shunting,[3] but in all four studies, randomization took place at some time, days to weeks, after presentation for bleeding, *i.e.*, beyond the period of the highest mortality. Emergency portacaval shunt has been advocated by Orloff and Bell[4] to treat cirrhotic patients with acute variceal bleed. The high operative mortality rate (40–50%) is a major deterrent to this procedure, particularly if used as a last resort.[5,6] However, patients with untreated active bleeding have comparable mortality rates,[7] and there are no controlled trials comparing emergency shunt with conservative medical therapy. Despite this lack of adequate data, a strong case has been made against emergency portacaval shunt.

Besides early recurrence, the severity of liver failure is the other major determinant of mortality rate in cirrhotic patients with variceal hemorrhage.[8] The prognosis in patients with severe liver disease is usually dismal and it seems unlikely that any therapeutic strategy can significantly improve their survival.

In this report, we describe our experience with emergency portacaval shunt in patients with variceal hemorrhage and mild to moderate liver disease. All patients were part of a negative clinical trial of propranolol, and

data were collected prospectively at the time of variceal rebleeding. Our results suggest that under well-defined conditions, emergency portacaval shunt is a valid therapeutic alternative.

Materials and Methods

During a 3-year period, 79 adult patients admitted to Saint-Luc Hospital for variceal hemorrhage were entered into a controlled trial of propranolol for the prevention of variceal rebleeding. During an average follow-up of 692 ± 78 days (mean ± SE), 62 of 79 patients rebled. The average interval between the first bleeding episode and rebleed was 91 ± 20 days. There was no difference in the rebleeding rate between patients treated with propranolol and patients treated with placebo. Detailed results of this trial have been published elsewhere.[9] The endpoint of the trial was rebleeding from varices. In patients who rebled, drug treatment was discontinued and alternative treatments were used. We decided *a priori* that, if possible, patients who rebled and who were in good condition would have an emergency central portacaval shunt, whereas patients with severe liver disease would be treated by endoscopic sclerotherapy with intravariceal ethanolamine. However, available alternatives were explained to the patient, who made the final decision. The 62 patients who rebled form the basis of this report.

The severity of liver disease at the time of rebleeding was assessed by the Child-Turcotte classification (CTC) as modified by Di Magno et al.[10] In this modification, each of five variables (ascites, encephalopathy, serum albumin, serum bilirubin, and prothrombin time) is given a value of 1, 2, or 3 for increasing abnormality, and the values summed over the five variables for each patient. Thus, the best possible score is 5 and the worst is 15. Mild liver disease (class A) is defined as a score of 5–7, moderate liver disease (class B) as a score of 8–10, and severe liver disease (class C) as a score of 11 or greater. Bleeding was treated initially with blood transfusions as required, and balloon tamponade if necessary until definitive treatment by surgery or sclerotherapy. Surgery was performed by one of four surgeons (LD, RL, ST, and PL) experienced with portacaval shunt surgery.

The diagnosis of hepatic encephalopathy occurring during follow-up was based on clinical criteria according to Trey et al.[11] Encephalopathy was categorized as "spontaneous" (not associated with specific comagenic events) or "induced" (precipitated by gastrointestinal bleeding, drug administration, infection, *etc.*). "Spontaneous" encephalopathy was further categorized as "mild" (easily managed by diet and lactulose or neomycin, not interfering with normal life function) or "severe" (precluding normal activities of daily living).[12]

Survival curves were constructed by the Kaplan-Meier method.[13] Multivariate analysis, using the Cox proportional hazard model[14] with a stepwise procedure was performed to identify variables that had an effect on survival.

Results

The outcome of the 62 patients who rebled from varices is shown in Figure 1. Nine patients died of massive hemorrhage at the time of rebleeding: two patients died at home and seven patients died in the hospital. Of the 53 patients who survived the hemorrhage, 42 had mild or moderate liver disease (CTC class A or B) and 11 had severe (class C) liver disease (Fig. 1).

Severe Liver Disease Group

Eight of the patients with severe liver disease were treated by repeated endoscopic sclerotherapy. All died within 4 months except one patient who had an hepatic transplantation. Three patients were treated by emergency portacaval shunt surgery: two patients chose surgery rather than sclerotherapy, and one patient had shunt surgery because of repeated bleeding after sclerotherapy. All three patients died within 30 days of surgery (2 of liver failure and 1 of sepsis).

Mild or Moderate Liver Disease Group

Of 42 patients with mild or moderate liver disease at the time of rebleeding, 36 had emergency shunt surgery. Two patients had devascularization surgery instead of a shunt because of portal vein thrombosis (1 patient died of postoperative complications and the other was alive at 1 year). The remaining four patients were treated by endoscopic sclerotherapy: one patient refused surgery, one patient had portal vein thrombosis, one patient was 96 years old and had cardiac failure, and a portacaval shunt turned out to be technically impossible at laparotomy in the fourth patient. Two of these four patients were alive at 1 year.

Of the 36 patients who had emergency surgery, 35 had a terminolateral portacaval shunt and one a central splenorenal shunt. Balloon tamponade was used in a majority of patients to control the bleeding episode and obtain hemodynamic stabilization before surgery (Table 1). The interval between the endoscopic diagnosis of variceal bleeding and surgery averaged 19 ± 3 hours (mean ± SE). In five patients, surgery was delayed for more than 48 hours because of infection (N = 4) or delayed patient's consent (N = 1). The operative mortal-

ity rate, defined as in-hospital mortality after surgery, was 19%: three patients died of sepsis, two patients died of liver failure, one patient died of adult respiratory distress syndrome, and one patient died of bleeding after shunt thrombosis. Hepatic encephalopathy occurred in 36% of patients (isolated "induced" episodes in 12% and "spontaneous" in 24%). Encephalopathy responded favorably to protein restriction and lactulose administration in all instances. One- and 2-year survival rates were 78% and 71%, respectively (Fig. 2).

TABLE 1. *Emergency Shunt Surgery in 36 Patients with Mild or Moderate Liver Disease*

Age (years, mean ± SE)	55 ± 2
Etiology of portal hypertension (no. of patients/%)

>48 hours	5 (14%)
Operative mortality (no. of patients/%)	7 (19%)

* According to DiMagno's modification of the Child-Turcotte classification, see text for details.

Prognostic Factors for Survival

Of the 53 patients who survived the rebleeding episode, 1- and 2-year survival rates were 60% and 56%, respectively. Prognostic variables for the duration of survival were examined by the Cox proportional hazard model. Potential variables examined included age, the severity of liver disease (CTC score), the presence of associated diseases (comorbidity), the presence of active alcoholism, the severity of the bleeding episode (number of transfusions required), and serum creatinine level. The severity of liver disease and serum creatinine level were the only variables found to be of prognostic significance ($p < 0.05$).

Discussion

Our data suggest that portacaval shunt is a valid alternative for the treatment of acute variceal hemorrhage, and that it can be applied in a majority of patients with mild or moderate liver disease, with good long-term results.

In this prospective study, we had planned to use emergency shunt in patients with mild to moderate liver disease. Emergency shunt was not used as a desperate measure in patients who continued to bleed despite conventional treatment, but rather systematically after hemodynamic stabilization and control of the bleed with balloon tamponade. Under these conditions, the operative mortality rate was 19%. The 1-year survival rate of 78% appears comparable to that of similar patients treated by sclerotherapy.[15,16]

Portacaval shunt was highly effective in preventing further variceal hemorrhage, as only one of 36 patients rebled from varices due to thrombosis of the shunt, but the drawback was a 36% incidence of postoperative hepatic encephalopathy. In all instances, encephalopathy responded favorably to protein restriction and lactulose, but was responsible for 13 hospital admissions over a 2-year period. Endoscopic sclerotherapy is not associated with such a high incidence of encephalopathy, but patients often need to be admitted for repeated bleeding until varices are eradicated.[15,17] The extent to which encephalopathy or repeated bleeding alter the quality of life of patients has not been examined.

Our results in patients with severe liver disease were catastrophic no matter which treatment was used. The only long-term survivor was a 28-year-old patient who had an hepatic transplantation 1 month after the bleeding episode. This observation re-emphasizes that the severity of the underlying liver disease is the key determinant to prognosis in variceal hemorrhage. The ominous nature of variceal hemorrhage is also illustrated by the number of patients who died of massive hemorrhage before any therapeutic intervention could be applied (15% in this study). These patients were identified because they were part of a prospective study on rebleeding. Some of them died at home, or in the hospital before any resuscitation measures could be initiated. In other settings, such patients would not be diagnosed and included in a descriptive study of variceal hemorrhage, leading to an underestimation of mortality due to variceal bleeding.

Cello et al.[18] compared emergency shunt with endoscopic sclerotherapy in patients with severe liver disease and found no difference in short-term (1-year) survival between the two groups. A preliminary report by the same investigators also suggests that there is no difference in total health care costs between the groups.[19] In their study, patients were designated as having severe (class C) disease according to the single worst criterion for class C of the five variables measured. In our study, 25 of the 42 patients that we classified as having mild or moderate disease would have been classified as having severe liver disease according to their definition. It is therefore difficult to compare different studies because of such methodological variations.

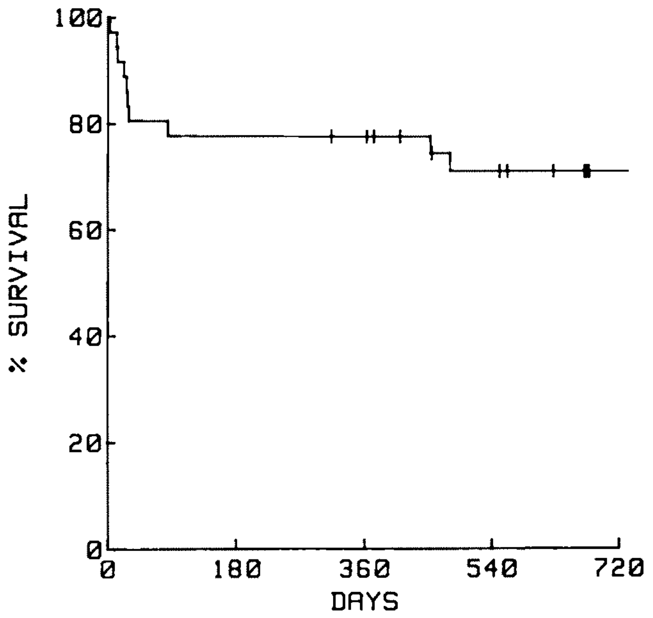

FIG. 2. Cumulative survival after emergency portacaval shunt surgery in 36 patients with mild or moderate liver disease. The short vertical bars represent trial times for patients still alive when last seen.

In summary, our data indicate that in patients with mild or moderate liver disease, emergency portacaval shunt results in an acceptable long-term survival rate. We suggest that emergency shunt surgery should be considered in such patients when other forms of treatment for the prevention of rebleeding have failed. A preliminary report by Warren et al.[20] also suggests that sclerotherapy followed by shunt surgery for sclerotherapy failure results in a significantly improved long-term survival.

FOR THE BEST DEFENSE AGAINST CANCER, SEE HIM ONCE A YEAR.

AND HIM ONCE A WEEK.

He may not look like everybody's idea of a cancer specialist.

But there's strong evidence that your greengrocer has access to cancer protection you won't find in any doctor's office.

Like broccoli. Peaches. Canteloupes. Spinach. And other sources of Vitamin A related to lowering the risk of cancer of the larynx and esophagus. Not to mention sweet potatoes, carrots, pumpkin, winter squash, tomatoes, citrus fruits and brussels sprouts.

Vegetables such as cabbage, broccoli, brussels sprouts, kohlrabi and cauliflower may help reduce the risk of gastrointestinal and respiratory tract cancer.

Fruits and vegetables (and whole grain cereals such as oatmeal, bran and wheat) may help lower the risk of colorectal cancer.

In short, make sure you do what your mother always told you to do. Eat your vegetables.

AMERICAN CANCER SOCIETY®

Weck introduces two
to make you throw away all

On the left is the lever-action VisiStat® stapler. On the right is the pistol-grip Weck 360LX® stapler. Both were designed to give you the best features of other skin staplers, without their disadvantages.

Both are members of the new Weckstat™ line of premier closure products, so you can now order the two most popular stapler styles from one source. And dispose of all the others for good.

VisiStat® stapler. The first lever-action stapler to combine superior visibility with reliable control.

While other lever-action staplers can either block your vision or hamper control, the new VisiStat® stapler enhances both.

The angle of the stapler head and position of the staple-forming anvil are designed to give you the clearest possible view of the staple during formation. The firing action is extraordinarily smooth and controlled, with no jarring recoil.

WECK

Members of the Weckstat™ family of closure products.

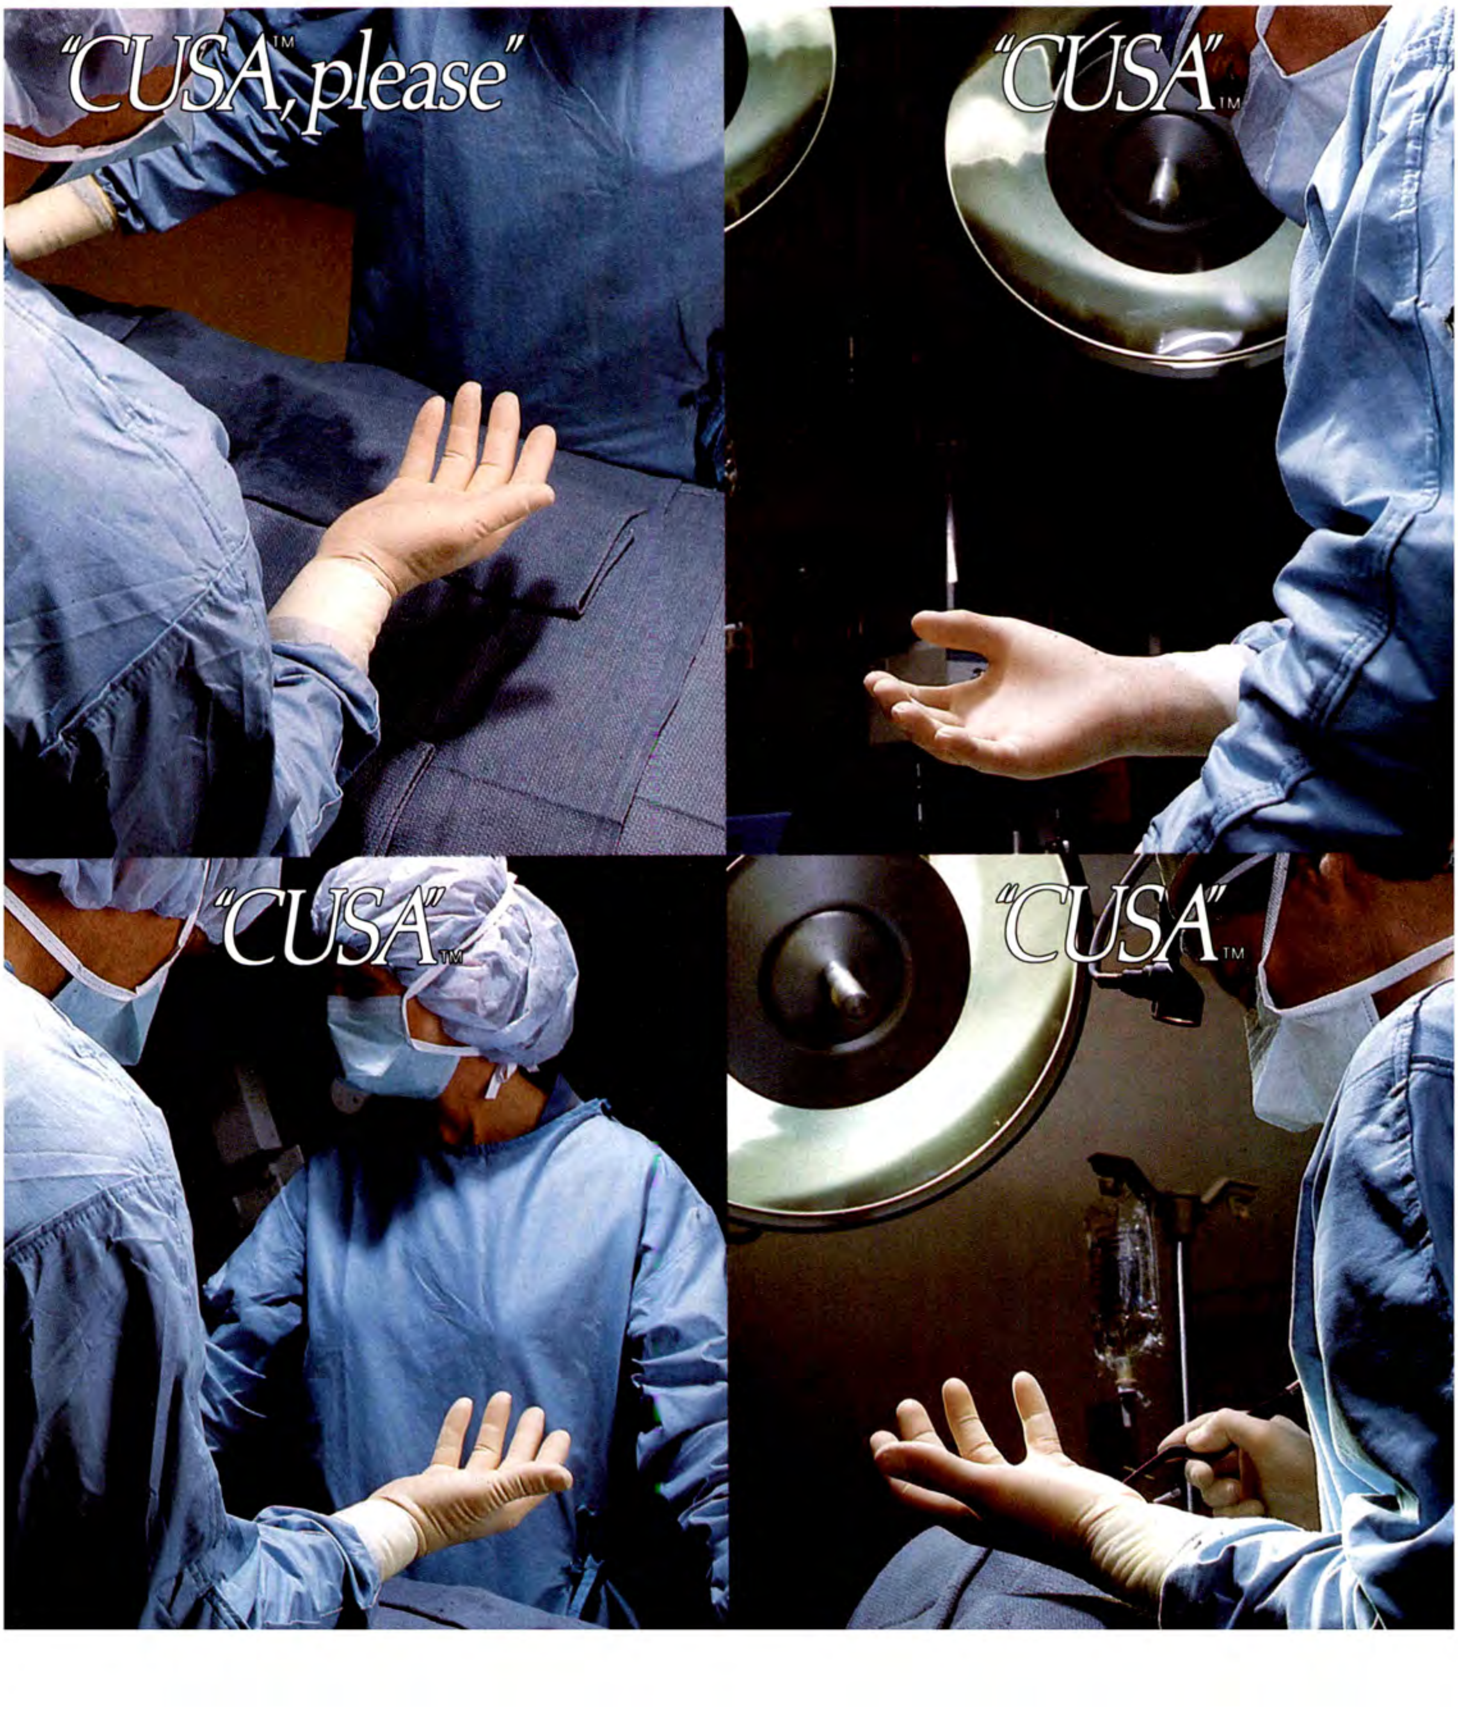
disposable staplers designed the others. Forever.

And the NonStop™ staple feed is designed for maximum reliability, closure after closure.

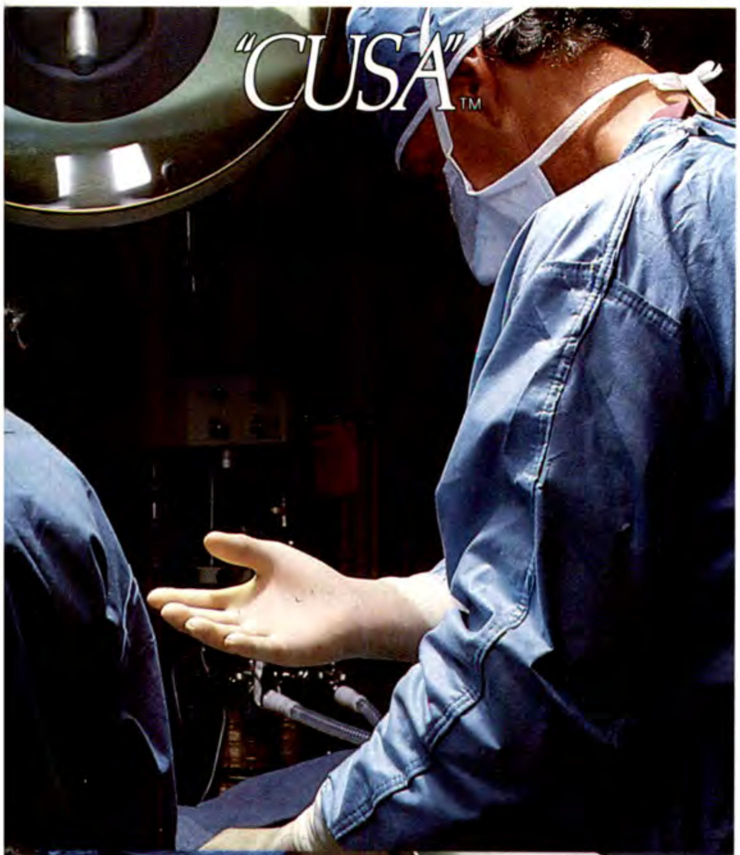
Get precise control of staple placement with the high-visibility Weck 360LX® stapler. While other pistol-grip staplers can make staple placement difficult to control, the Weck 360LX® stapler makes it easy.

The head of the stapler rotates 360° on a centered axis for access to hard-to-reach areas. The L-shaped handle has an ideal trigger span for control of staple closure. Staples are clearly visible as they form to further enhance accuracy of placement. And the Weck 360LX® stapler is the *only* pistol-grip style with a straight-stack feeding mechanism for reliable staple delivery. So whether you prefer a pistol-grip or a lever-action stapler, the only name you need to remember now is Weck. For details, contact your Weck Representative or call (800) 334-8511.

In ultrasonic surgery,



one name is a given.



In thousands of operating rooms around the world, the Cavitron Ultrasonic Surgical Aspirator–CUSA™–is synonymous with ultrasonic surgery. Already well-established in neurosurgery for rapid, efficient tumor removal, the CUSA™ is now proving itself indispensable as an ultrasonic scalpel in general surgery for liver, colorectal, and oncologic procedures.

Indeed, an overwhelming number of CUSA™ users–97% in a recent survey*–have expressed their high level of satisfaction with this system.

There is only one CUSA,™ and only Cavitron can support it with almost 40 years of experience as the world leader in ultrasonic surgical technology. It is no wonder, then, that surgeons have called for the CUSA™ in over 100,000 successful procedures.

INTERNATIONAL SYMPOSIUM ON SARCOMAS
AT INNISBROOK, TARPON SPRINGS, FLORIDA
OCTOBER 8-10, 1987

Program Chairman: James R. Ryan, M.D.
Intergroup Sarcoma Committee

The first international symposium, to date, involving all of the disciplines treating sarcomas, this is a planned interdisciplinary program including orthopaedic surgeons, general surgeons, medical oncologists, pediatric oncologists, radiation oncologists and pathologists. The program is designed as didactic lectures followed by panel discussions to stimulate educational debate as to the different forms of treatment for sarcomas.

Comparison of Intraoperative Ultrasonography and Cholangiography in Detection of Small Common Bile Duct Stones

RASHMAE CHARDAVOYNE, M.D., SHEILA KUMARI-SUBHAYA, M.D., LOUIS J. AUGUSTE, M.D., GAIL PHILLIPS, M.D., THEODORE A. STEIN, M.S., and LESLIE WISE, M.D.

High-resolution intraoperative ultrasonography was compared with conventional radiographic imaging in the detection of small common bile duct (CBD) stones (<5 mm in diameter). Sixteen mongrel dogs had laparotomy and ligation of distal CBD; 1 week to 10 days later, 0–3 gallstones of varying sizes (2–5 mm) were introduced into the dilated CBD (6–16 mm). High-resolution intraoperative ultrasonography of the CBD and a conventional intraoperative cholangiogram were performed to detect the presence and number of stones. The results of these two tests were evaluated independently by two ultrasonographers and two surgeons. There were 21 true-positive and five false-negative readings by sonogram compared with 17 and 9, respectively, by cholangiogram. Sensitivity of the sonogram was 81% and 65.4% by cholangiogram. Score of accuracy was 1.06 and 1.62 by cholangiogram and 0.81 and 0.87 by ultrasound ($p < 0.05$). Intraoperative ultrasonography was found to be more sensitive in detecting small CBD stones when compared with intraoperative cholangiogram.

COMMON BILE DUCT (CBD) explorations are performed in 10–15% of all routine cholecystectomies.[1] The incidence of unsuspected CBD stones varies from 4–10% even in the absence of traditional clinical indications for CBD explorations.[2-4] The routine use of intraoperative cholangiography has allowed a 50% reduction in the number of CBD explorations with a concomitant two- to three-fold increase in a positive yield.[5-9] Yet despite a routine completion T-tube cholangiogram after a CBD exploration, the incidence of retained common duct stone remains about 4–7%.[10,11] In an attempt to reduce further the incidence of this complication, intraoperative ultrasonography has been suggested as a more accurate method of detecting CBD stones at the time of surgery.[11-19] However, its accuracy when dealing with small stones has been questioned.[18] The aim of this study was to compare high resolution ultrasonography with conventional radiographic imaging in the detection of small CBD stones (<5 mm) in ducts of varying sizes.

From the Long Island Jewish Medical Center, New Hyde Park, and State University of New York at Stony Brook, Stony Brook, New York

Materials and Methods

Human gallstones were obtained from patients at elective cholecystectomy. Twenty-two stones were measured in the greatest diameter. Four stones were 2 mm, seven stones were 3 mm, six stones were 4 mm, and five stones were 5 mm in diameter. Sixteen healthy mongrel dogs weighing between 10 and 20 kg were housed in a thermoregulated environment (23 C) and received dog chow (Ralston Purina Co., St. Louis, MO) and water *ad libitum*. After an overnight fast, the dogs were anesthetized with an intravenous administration of 30 mg of sodium pentobarbital per kilogram of body weight. Under sterile conditions, a midline laparotomy was performed. The CBD was identified and dissected free. A 2-0 silk ligature was placed around the distal CBD to cause dilation of the biliary tract since the normal canine bile duct is too small to admit a 5-mm gallstone. After a period of recovery of 5–10 days, the dogs had a second laparotomy under sodium pentobarbital anesthesia. At this time the CBD measured 6–16 mm in diameter with a mean of 9.5 mm (Table 1). This is comparable to a human CBD. The silk ligature around the distal common bile duct was removed. Human gallstones measuring 2–5 mm were introduced in varying numbers (0–3) into the CBD through a duodenotomy (Table 1). A high-resolution ultrasonography was performed using a 7.5-MHz small parts transducer with a

short focal length to detect the presence and number of stones in the CBD. Direct contact scans were performed. The transducer was covered with a sterile glove and the CBD was scanned directly using sterile saline in the field. This was followed by a conventional intraoperative cholangiogram. A 25% Hypaque® solution was injected *via* a catheter placed in the CBD through the duodenotomy. The results of the ultrasonographic and x-ray studies were evaluated blindly and independently by two ultrasonographers and two surgeons. The two methods were compared using the incidence of true-positive, true-negative, false-positive, and false-negative as defined in Table 2. Accuracy of both methods was evaluated by using a scoring technique. When the correct number of stones were identified, a score of zero was given. When the number of stones was greater or lesser than the actual number, the score was given as the absolute difference between the observed number and the actual number (*e.g.*, if the actual number was 1 and the observer read it as 3, then the score given was 2).

TABLE 2. *Definitions*

True (+) (TP)	Stones in the duct and read as stones.
True (−) (TN)	No stone in the duct and read as no stone.
False (+) (FP)	No stones but read as stones.
False (−) (FN)	Stones in the duct and read as no stones.

TP = true-positive; TN = true-negative; FP = false-positive; FN = false-negative.

TABLE 3. *Comparison of Intraoperative Cholangiogram and Ultrasound in Detection of Small CBD Stones*

	No. of Observations

Predictive Value Of:	Ultrasonography	Cholangiography
A positive test $\left(\frac{TP}{TP + FP}\right)$	84%	85%
Sensitivity $\left(\frac{TP}{TP + FN}\right)$	81%	65.4%
Specificity $\left(\frac{TN}{TN + FP}\right)$	33%	50%
Efficiency $\left(\frac{TP + TN}{\text{All tests}}\right)$	72%	62.5%

TP = true-positive; FP = false-positive; TN = true-negative; FN = false-negative.

Results

The mean time required for the actual intraoperative testing was similar for both techniques. Neither high-resolution ultrasonography nor intraoperative cholangiography detected gallstones in the CBD in 100% of the dogs. Ultrasonography yielded 65.6% true-positive and 15.6% false-negative readings compared with 53.1% true-positive and 28.1% false-negative readings for intraoperative cholangiogram (Table 3). In 53% of the dogs, ultrasonography correctly quantitated the number of stones present regardless of the size of the stones. In contrast, conventional intraoperative cholangiography detected the actual number of stones in only 25%. The predictive value of ultrasonography to detect small stones in the CBD was 84% with a sensitivity of 81% (Table 4). For intraoperative cholangiography, the predictive value of the positive test was 85% but its sensitivity was only 65%. The score of accuracy was 1.06 and 1.62 by cholangiography, which was less accurate than ultrasonography. The score of accuracy by ultrasonography was 0.81 and 0.87 (Table 5).

Discussion

The use of routine cystic duct cholangiography has significantly reduced the incidence of negative CBD explorations.[5-9] Intraoperative ultrasonography of the CBD to detect the presence of CBD stones has been shown to be equally effective.[13,15-17] However, with ei-

ther of these techniques the small size of the CBD stone has been a limiting factor.[18] The validity of this data is questionable for lack of long-term observation of these patients. In a follow-up study on 152 patients with residual intraductal calculi, Hicken and McAllister[10] showed that the initial clinical course provided little information concerning the presence of overlooked stones. In the same study, within 18 months, 60% of the remaining 132 patients required a second operation. With a 5-year follow-up of these patients, 96% or 143 patients required secondary exploration. There were five operative deaths associated with re-exploration of the bile ducts. With the advent of percutaneous extraction of these retained stones, the mortality and morbidity have been decreased but not eliminated. This is why every attempt should be made at the initial operation to remove all possible stones in the CBD. We have shown in this study that the intraoperative use of ultrasound is more sensitive in detecting small CBD calculi compared with the routine cholangiogram. The other advantage of this technique is that there is no radiation hazard, and the probe can be used for as long as necessary to detect the stones. The time required for both procedures was found to be the same in this study.

Our study presents the advantage of verifying the accuracy of these tests as the exact number of stones introduced in each duct was known. Indeed, with intraoperative cholangiogram, nine CBD stones would have been left behind compared with five that would have been left behind by ultrasound. The four false-positive tests by sonogram and three by cholangiogram were considered to be due to the presence of air bubbles. Air bubbles can occur in the CBD during stone introduction by the technique used in this study and interfered more with the ultrasonographic readings. Since no accidental introduction of air into the biliary tree will occur clinically, a much higher specificity than that found in this experimental model would be expected.

The disadvantage of ultrasound is noted to be the need for trained personnel. In previous studies[15-17] it has been shown that with time and familiarity with the technique, surgeons can learn to interpret the findings, thus eliminating the need for a trained ultrasonographer.

In summary, we have presented the results of a comparison between conventional intraoperative cholangiography and ultrasonography in detection of small (<5 mm in diameter) CBD stones. We found intraoperative ultrasound to be more sensitive in detecting small CBD stones compared with intraoperative cholangiography.

Protein and Energy Metabolism with Biosynthetic Human Growth Hormone after Gastrointestinal Surgery

H. C. WARD, D. HALLIDAY,* and A. J. W. SIM

The effect of biosynthetic human growth hormone (BSHGH) on postoperative protein and energy metabolism has been studied in patients who had major gastrointestinal surgery. Seven patients received placebo and seven patients received BSHGH, 0.1 mg/kg/24 h, for the first six postoperative days. Mean total nitrogen excretion was significantly lower with BSHGH (31.5 ± 2.4 g N) (2287 ± 160 mmol) than with placebo (42.7 ± 3.1 g N) (3049 ± 219 mmol) over the 6-day study period. The mean daily measured energy expenditure over days 3–6 was higher with BSHGH (31.3 ± 1.8 kcal/kg LBM/24 h) (131 ± 7 kJ/kg LBM/24 h) than with placebo (27.6 ± 0.8 kcal/kg LBM/24 h) (114 ± 2 kJ/kg LBM/24 h). Fat oxidation with BSHGH (2.05 ± 0.26 mg/kg LBM/24 h) was greater than with placebo (1.5 ± 0.17 mg/kg LBM/24 h) and protein oxidation was less with BSHGH (0.68 ± 0.07 g/kg LBM/24 h) than with placebo (0.9 ± 0.09 g/kg LBM/24 h) on days 1–6. Postoperative nitrogen turnover (BSHGH 943 ± 174 mg N/kg LBM/24 h, placebo 557 ± 50 mg N/kg LBM/24 h) (BSHGH 67 ± 13 mmol/kg LBM/24 h, placebo 40 ± 4 mmol/kg LBM/24 h), protein synthesis (BSHGH 5.31 ± 1.09 g prot/kg LBM/24 h, placebo 2.54 ± 0.33 g prot/kg LBM/24 h) and protein breakdown (BSHGH 5.90 ± 1.09 g prot/kg LBM/24 h, placebo 3.48 ± 0.31 g prot/kg LBM/24 h) were greater with BSHGH. On the first postoperative day serum insulin and blood glucose levels were higher with BSHGH than with placebo, and on days 4 and 7 serum somatomedin-C levels were significantly elevated. This study shows that BSHGH alters postoperative protein and energy metabolism by reducing protein oxidation and increasing fat oxidation with raised rates of whole body nitrogen turnover.

From the Academic Surgical Unit, St. Mary's Hospital, London, and the Division of Clinical Sciences, Clinical Research Centre, Harrow, England*

CUTHBERTSON'S DESCRIPTION of increased excretion of nitrogen, sulphur, phosphorus, and calcium after injury, which implied breakdown and oxidation of protein greater than could be accounted for by damage at the injury site alone, has led to the concept that a systemic response to injury exists.[1] This results in increased protein and energy substrate oxidation and an increased metabolic rate.[2] Neuronal and hormonal factors have been implicated in the mediation of this response.[3] The net effect of these changes is to erode protein and energy substrate stores at a time when nutritional intake is often reduced. If these resources are already reduced at a time of injury, the ability to heal wounds, combat infection, and breathe adequately may be impaired, leading to increased morbidity and mortality.[4] Even the well nourished may experience periods of debility after the injury of major surgery, which may relate to reduction of protein reserves and energy stores.[5]

Shortly after its identification, growth hormone was shown to have anabolic effects on protein metabolism, and Cuthbertson et al. were able to abolish negative nitrogen balance in fed rats subjected to fracture of the femur by using a bovine pituitary extract.[6] Human pituitary growth hormone has been investigated in the context of surgery by Johnson and Hadden[17] and Roe and Kinney[8] and in major burns by Soroff et al.[9] and Wilmore et al.[10] Further study has been limited by the availability of human pituitary hormone. Biosynthetic human growth hormone (BSHGH) (Somatonorm, KabiVitrum, Stockholm, Sweden) produced by recombinant DNA technology from an *Escherichia coli* host, has become available recently. BSHGH is identical to human growth hormone but with the addition of a methionyl residue at the N-terminal position.

This study investigates the effects of BSHGH on energy substrate and whole body protein metabolism in patients who have major gastrointestinal operations without nutritional support.

LBM = lean body mass. A/P = abdominoperineal.

Patients and Methods

Sixteen patients due to have major gastrointestinal surgery were allocated at random to receive 0.1 mg/kg of BSHGH or placebo by intramuscular injection at 8:00 P.M. on the day of operation and at the same time for the following 6 postoperative days. Patients who were diabetic, had disturbed liver function, were taking steroids, had sepsis, weight loss of more than 10%, or disseminated malignancy were not considered for study. Two patients had development of septic complications during the course of the study and were excluded from further analysis. Seven patients received BSHGH and seven patients received placebo. The details of sex, age, weight, and lean body mass (LBM) from skinfolds,[11] diagnosis, and operative procedures are shown in Table 1. All patients had an uncomplicated postoperative course during the study. Postoperative analgesia was provided by continuous intravenous morphine sulphate (six in each group) or by morphine epidural injection.

In the preoperative studies, patients were allowed fluids by mouth, to provide 400 kcal/24 h with negligible nitrogen intake. After operation they received a regimen of saline and 5% dextrose solution providing 400 kcal/24 h (1675 kJ/24 h). Water by mouth was introduced when indicated and dietary intake was begun after the sixth day.

Blood samples were drawn for substrate and hormone levels on the control day before operation and on the first, fourth, seventh, and ninth postoperative days between 8:00 A.M. and 9:00 A.M.

Indirect calorimetry was done before operation and on the first 6 postoperative days between 10:00 A.M. and 12:00 P.M. Resting energy expenditure (REE) was determined from oxygen consumption and carbon dioxide production, using Weir's formula.[12] Oxygen and carbon dioxide concentration were measured with paramagnetic and infrared analysers, respectively, gas flow was measured by a Fleisch pneumatochograph incorporated in a mobile system giving a visual display and a continuous printout of results (Calostar, Fenyves & Gut, Basel, Switzerland[13]). Rates of substrate oxidation were calculated from oxygen consumption, carbon dioxide production, and urinary nitrogen excretion by MacHattie's formulae.[14]

Urine for total nitrogen excretion was collected throughout the study period. Total nitrogen was measured by a semiautomated Kjeldahl technique. Nitrogen turnover was measured before operation and on the third to fourth postoperative days using a primed continuous infusion of ^{15}N glycine for 24 hours.[15] Isotope enrichment of urinary urea over the second 12-hour period of infusion was measured by mass spectrometry. Whole body nitrogen turnover was calculated by dividing the infusion rate of ^{15}N tracer by the urinary urea enrichment with ^{15}N at plateau.[16] Whole body protein synthesis was derived by subtracting total urinary nitrogen excretion from turnover. In the absence of nitrogen

TABLE 2. *Total Urinary Nitrogen Excretion, g N/24 h (mmol/24 h)*

Day	0	1	2	3	4	5	6

intake, whole body protein breakdown corresponds to the rate of nitrogen turnover. Synthesis and breakdown values are converted to grams of protein by multiplying by 6.25. Serum growth hormone, insulin, and somatomedin-C were each measured by radioimmunoassay. Blood glucose was measured by the glucose oxidase method. Results are expressed as mean and SEM. Statistical analysis is nonparametric by the Mann-Whitney U test.

Informed consent was obtained from the patients and the study was approved by the District Ethical Committee.

Results

No adverse effects attributable to the studies or the giving of placebo or BSHGH were encountered. For technical reasons, nitrogen turnover studies were not completed in the preoperative period on three patients (2 placebo, 1 BSHGH) and one patient (BSHGH) in the postoperative period. Total nitrogen excretion over the first 6 postoperative days was 31.5 ± 2.4 g (2267 ± 160 mmol N) for those receiving BSHGH, significantly less than 42.7 ± 3.1 g (3049 ± 219 mmol N) for those with placebo ($p < 0.01$). Results for each day are shown in Table 2 and Figure 2. The mean REE on days 1 and 2 of 28.8 ± 1.4 and 31.7 ± 1.8 kcal/kg LBM/24 h (121 ± 6 and 133 ± 9 kJ/kg LBM/24 h) with placebo and BSHGH, respectively, were not significantly different, but over days 3–6 the REE of 31.3 ± 1.8 (131 ± 7 kJ/kg LBM/24 h) with BSHGH was significantly higher than that with placebo (27.6 ± 0.8, $p < 0.05$) (114 ± 2 kJ/kg LBM/24 h). Although respiratory quotient over days 1–6 was consistently lower in patients receiving BSHGH (0.79 ± 0.02) than patients receiving placebo (0.81 ± 0.02), the difference was not significant. Fat oxidation (BSHGH 2.05 ± 0.26 g/kg LBM/24 h and placebo 1.51 ± 0.17) was significantly higher with BSHGH (Fig. 1). Carbohydrate oxidation (BSHGH 2.10 ± 0.36 g/kg LBM/24 h and placebo 2.09 ± 0.36) was similar and corresponded to dextrose infusion rates of 2.11 ± 0.21 g/kg LBM/24 h for BSHGH and 2.12 ± 0.17 for placebo; protein oxidation (calculated from nitrogen excretion, Fig. 2) was significantly lower with BSHGH than with placebo (0.68 ± 0.07 g/kg LBM/24 h and placebo 0.92 ± 0.09, mean for days 1–6, $p < 0.05$).

Whole body nitrogen turnover, protein synthesis, and breakdown results are shown in Table 3. All values were similar in the preoperation period but after operation, nitrogen turnover, protein synthesis, and breakdown rates were significantly higher in the group receiving BSHGH. In five patients receiving placebo and six patients receiving BSHGH in whom nitrogen turnover was measured before and after operation, turnover decreased to a mean of 75% (range: 61–87%) of control in those with placebo, whereas with BSHGH turnover in-

Before operation	6	764 ± 66 (55 ± 51)	4.04 ± 0.48	4.78 ± 0.41
After operation	6	943 ± 174* (67 ± 13)	5.31 ± 1.09*	5.90 ± 1.09*
Placebo				
Before operation	5	815 ± 78 (58 ± 6)	4.31 ± 0.54	5.09 ± 0.44
After operation	7	557 ± 50 (40 ± 4)	2.54 ± 0.33	3.48 ± 0.31

* $p < 0.05$ (Postoperative placebo *vs.* postoperative BSHGH).

creased to a mean of 126% (range 81–212%). After operation, whole body protein synthesis expressed as a percentage of breakdown was higher with BSHGH (89 ± 3) than placebo (72 ± 5, $p < 0.05$). The preoperative values were 84 ± 4 and 84 ± 3, respectively.

Serum growth hormone, somatomedin-C, and insulin were all raised in those receiving BSHGH as shown in Table 4. Elevations in serum growth hormone and insulin levels were significant on the first postoperative day and returned to control values by the ninth day, 3 days after the study period. The raised levels of somatomedin-C in patients receiving BSHGH became significant on the fourth and seventh days and were still significantly higher than those of patients receiving placebo on the ninth day. These changes in hormonal profile were accompanied by elevated blood glucose in patients receiving BSHGH (Table 4), which was sufficient to produce slight glycosuria in some patients.

Discussion

The reduction in nitrogen excretion and elevation of metabolic rate and of fat oxidation shown in this study are in keeping with the findings of Cuthbertson et al.[6] and of Roe and Kinney,[8] confirming that BSHGH has similar metabolic effects to growth hormone derived from pituitary glands. In contrast, the study of Johnston and Hadden failed to show an improvement in nitrogen balance with pituitary growth hormone after herniorrhaphy.[7] The lesser degree of trauma, and resulting magnitude of negative nitrogen balance, occurring with hernia repair may explain the difference from the current study. Soroff et al.[9] and Wilmore et al.[10] both demonstrated increased retention of nitrogen, elevation of metabolic rate, and decreased respiratory quotient in severely burned patients given growth hormone.

Initially, Wilmore suggested that adequate nutritional

intake was necessary for growth hormone to produce a nitrogen sparing effect; but more recent data from Manson and Wilmore,[17] obtained from studies on healthy human subjects receiving hypocaloric intravenous feeding, have refuted this. They have demonstrated that with an intake of 1070 kcal/d and 11.3 g N/d growth hormone improves nitrogen retention and increases fat oxidation. The results of this study indicate that growth hormone can alter metabolism with minimal (400 kcal/24 h) (1675 kJ/24 h) nutritional intake.

Nitrogen balance is an index of net whole body protein balance. If whole body nitrogen turnover is measured, nitrogen intake and excretion can be used to derive rates of whole body protein synthesis and breakdown.[16] The ^{15}N from glycine has been shown to be widely distributed among the other amino acids,[18] and although growth hormone has been shown to decrease the plasma level of most amino acids[19] there does not appear to be a specific effect on glycine metabolism. In the absence of evidence for a specific metabolic pathway between glycine and urea (which is affected by growth hormone to produce a decrease in transfer of the amino nitrogen of glycine to urea), the decrease in ^{1} N enrichment of urinary urea from which the increase in nitrogen turnover with growth hormone is derived is interpreted as being an effect on whole body protein metabolism and not a specific effect of growth hormone on glycine metabolism.

The improved nitrogen balance seen with administration of growth hormone occurs with a postoperative protein synthesis rate of 209% of the corresponding synthetic rate for placebo and a breakdown rate of 170% of placebo, indicating a relative increase in synthesis to breakdown of 39%. In the absence of exogenous protein intake, the amino acids for protein synthesis will be derived from breakdown and the expression of synthesis as a percentage of breakdown will give a value for the recycling of protein and, hence, the efficiency of protein metabolism. After operation there was a decrease in recycling of protein of 12% compared with before operation in the placebo group and an increase of 5% with growth hormone, there being a 17% improvement in the efficiency of protein metabolism after surgery when growth hormone is given.

The diversion of amino acids as potential gluconeogenic substrates from oxidative to synthetic pathways when growth hormone is given results in a reduction of a mean of 51 kcal/d (214 kJ/d) derived from protein oxidation. The increased energy production of 264 kcal/d (1105 kJ/d) from fat oxidation is in excess of that required to compensate for the shortfall from protein oxidation by a mean of 213 kcal/d (892 kJ/d). It is likely that this excess in oxidation of fat is a result of the specific action of growth hormone on increasing lipolysis and free fatty acid oxidation.[19] This is seen as an overall increase in energy expenditure, most notably in the last 4 days of the study.

A diabetogenic effect of growth hormone producing increases in blood glucose and serum insulin has been described[19] and is confirmed in this study. Serum levels of growth hormone, somatomedin-C, and insulin were all affected by growth hormone administration. Growth hormone stimulates secretion of somatomedin-C from the liver[20] and the gradually increasing levels of somatomedin-C during growth hormone administration suggest a direct action of growth hormone. Insulin levels are highest when blood glucose peaks and decreases as the glucose levels fall, suggesting that insulin levels are not primarily affected by growth hormone administration but relate to the blood glucose level. Because both somatomedin-C and insulin are capable of increasing rates of protein synthesis it is not possible to determine in this study if the elevated levels of either hormone, or growth hormone itself, are responsible for the raised rate of protein synthesis.

These studies were designed to investigate the effect of growth hormone administration on postoperative metabolism and have clearly demonstrated improved protein economy and increased fat oxidation in patients with minimal nutritional intake. The suggestion that somatomedin-C is a mediator of the protein responses is worthy of further investigation; however, this will only be possible if somatomedins can be synthesized and produced in sufficient quantites by recombinant DNA technology. This study has not specifically studied clinical outcome but it is unlikely that this will be affected by these metabolic changes. The importance of the data obtained here is to provide information that can be used to evaluate the effect of growth hormone on nutrient (particularly intravenous) utilization in not only producing more efficient use of expensive materials but perhaps in reducing the quantities of nutrients that require administration, thus allowing greater use of peripheral (as opposed to central) vein feeding.

Acknowledgments

The authors thank David Teale for carrying out estimations of somatomedin-C levels and Professor H.A.F. Dudley for advice concerning the study and its presentation.

Digital Ischemia as a Manifestation of Malignancy

LLOYD M. TAYLOR, JR., M.D., MICHAEL G. HAUTY, M.D., JAMES M. EDWARDS, M.D., and JOHN M. PORTER, M.D.

From the Division of Vascular Surgery, Oregon Health Sciences University, Portland, Oregon

The association of malignancy with thrombotic disorders of the arterial and venous systems is well described. To date, however, there are only 23 published case reports of digital gangrene associated with malignancy. During a prospective evaluation of over 700 patients with finger ischemia, there were five patients with finger gangrene associated with malignancy. Detailed clinical and laboratory evaluation, including detailed immunologic survey and hand angiography, allowed establishment of the precise mechanisms responsible for vascular occlusions in each patient. Three mechanisms were identified: arteritis, hyperviscosity, and hypercoagulability. Digital gangrene associated with malignancy is a rare condition, the mechanism for which can be deduced by careful diagnostic evaluation.

THE OCCASIONAL ASSOCIATION of diseases of the vascular system with systemic neoplasia has been recognized for over a century. The earliest reported paraneoplastic syndrome involving the vascular system was Trousseau's description in 1865 of femoral vein thrombosis, which he termed phlegmasia alba dolens, and occult carcinoma.[1] Venous thrombosis associated with carcinoma has been reported subsequently, frequently being termed "thrombophlebitis migrans."[2–4]

Descriptions of the remote effects of neoplasms on the arterial system have increased in frequency and variety in the past several decades.[5,6] Hairy cell leukemia has been associated with classic polyarteritis nodosa.[7] Symptoms of central nervous system granulomatous angiitis have preceded the diagnosis of Hodgkin's disease in at least several patients.[8,9] Johnson et al.[10] have described vasculitis involving nutrient arteries of nerves, which may explain the frequently observed relationship of mononeuritis monoplex with small cell carcinoma and lymphoma. Ischemic tissue necrosis, possibly caused by hyperviscosity, has been reported in a patient with chronic granulocytic leukemia.[11] Cryoglobulinemia and multiple myeloma associated with Raynaud's syndrome were reported as early as 1933.[12,13]

The coexistence of digital ischemia and carcinoma was first reported in 1884 by O'Connor. He described a middle-aged woman with breast cancer and presumed left supraclavicular metastases who had gangrenous fingertips.[14] Seven years later, Fagge and Pye-Smith described a young woman with digital ischemia who was found to have a locally infiltrating tumor mass involving the first dorsal sympathetic nerve at necropsy. The patient died within 1 year of onset of symptoms. The authors hypothesized that the digital ischemia was caused by local tumor invasion or metastases to the cervical sympathetic trunk.[15]

To our knowledge there have been 23 published case reports linking digital ischemia and malignant disease. The ischemic changes have been generally bilateral, symmetric, and have involved the upper extremities. Most of the reports have described single patients, with variable, usually sparse, accompanying laboratory data. These reports are summarized in Table 1.

In the past 15 years during a prospective evaluation of over 700 patients with upper extremity ischemia, we found five patients to have finger gangrene occurring in association with systemic malignancy. Each of these patients had detailed evaluation, including magnification

TABLE 1. *Case Reports Associating Digital Ischemia with Malignancy*

Case #	Date	Author	Sex	Age	Malignancy Type	Symptoms	Course
1	1866	Fagge and Pye-Smith[15]	F	"young"	CNS metastases, 1st dorsal nerve and sympathetic trunk metastases	Blue, cold, painful fingers	Died within 1 year
2	1884	O'Connor[14]	F	"middle aged"	Breast carcinoma	Gangrene: fingertips	Left supraclavicular metastasis
3	1901	Pasteur and Price-Jones[33]	M	61	Gastric carcinoma	Cold, blue extremities, Raynaud's	?
4	1920	Hamilton[34]	M	54	Esophageal carcinoma	Typical Raynaud's syndrome	?
5	1928	Bennett and Poulton[23]	M	61	Occult gastric carcinoma	Raynaud's syndrome	Died during cervical sympathectomy
6	1961	Domz and Chapman[27]	F	56	Adenocarcinoma right lung, myelofibrosis, cryoglobulins	Digital ischemia, gangrene fingertips	Symptoms resolved with tumor resection
7	1963	Nielson and Petri[24]	F	77	Colon carcinoma, cervical sympathetic and stellate ganglion metastasis	Symmetrical gangrene: fingers	Died
8	1959	Hawley et al. (1967)[35]	F	59	Anaplastic carcinoma of maxillary antrum	Painful, numb, gangrene digits	Died in 4 months
9	?	Hawley et al. (1967)[35]	F	54	Hypernephroma	Cold, numb, painful fingers	Return of pulses, healing of lesions, died within months
10	1964–1965	Hawley et al. (1967)[35]	F	45	Rectal/colon carcinoma, cystic ovarian tumor	Raynaud's syndrome	Died within 11 months of symptoms despite tumor resection
11	1957	Hawley et al. (1967)[35]	F	45	Adenopapillary ovarian carcinoma with metastasis	Numb, cold hands	Radiation therapy, symptoms resolved
12	1965–1966	Hawley et al. (1967)[35]	F	58	Pancreatic/ovarian carcinoma	Pain, numb, pallor: fingers	Died in 8 months
13	1953–1954	Hawley et al. (1967)[35]	F	42	Hodgkin's disease	Pain, tingling, blue fingers	Chemotherapy, radiation
14	1965–1967	Friedman et al.[25]	F	32	Epidermoid carcinoma, cervix, stage 1, ankylosing spondylitis	Raynaud's syndrome, right leg gangrene upper extremity	Symptoms improved with excision and radiation therapy
15	1966	Friedman et al.[25]	F	57	Anaplastic breast carcinoma with nodes	Ischemia and gangrene fingers and feet, bilateral thigh amputation	Symptoms resolved 22 months after mastectomy
17	1970	Powell (1973)[36]	M	7	Acute lymphocytic leukemia	Raynaud's syndrome	Remission of symptoms after chemotherapy and radiation therapy
18	1974	Palmer and Vedi[6,37]	F	62	Reticulum cell sarcoma	Finger cyanosis, bilateral splinter hemorrhages	Death months after onset of symptoms
19	1974	Palmer and Vedi[6,37]	F	74	Intra-abdominal carcinoma	Numbness, tingling and cyanosis bilateral fingers	Death months after onset of symptoms
20	1974	Palmer and Vedi[6,37]	F	66	Gastric carcinoma	Cold, blue fingers	Symptoms resolved after resection
21	1976–1977	O'Donnell et al. (1980)[28]	M	9	Acute myelocytic leukemia	Foot necrosis 9/76	Died 11/77: right main pulmonary artery thrombus
22	1978–1977	O'Donnell et al. (1980)[28]	M	52	Poorly differentiated adenocarcinoma, Buerger's disease	Claudication, great toe necrosis, brachial artery thrombosis	Died 1/79
23	1983	Wytock et al.[38]	F	59	Adenocarcinoma of ileum	Digital ischemia	Resolution of symptoms, resection × 5 years

hand arteriography and skin biopsy in three of the five patients and detailed laboratory screening for collagen vascular disease and coagulation abnormalities in all five patients. Our experience with the diagnosis and management of these patients forms the basis for this report.

Anticardiolipin antibody*
Platelet count
Serum triglycerides
Serum cholesterol
Blood viscosity
Urine protein
Cold agglutinins
Cryoglobulin
Cryofibrinogen
Anti-DNA

* Not routinely obtained.

Diagnostic Evaluation

Our approach to the diagnostic evaluation of patients with severe finger ischemia is standardized and has been previously reported.[16–19] Each patient has had pharmacodynamic magnification hand arteriography and/or noninvasive digital vascular examinations to identify and quantitate digital arterial obstruction and/or vasospasm. Biopsy specimens of affected tissue were obtained for routine histologic examination and immunofluorescent staining. In addition, a standard panel of laboratory tests as outlined in Table 2 was obtained.

Case Reports

Case 1

This 53-year-old woman had a history of 11 years of episodic digital color changes with cold exposure. There was a family and personal history of neurofibromatosis, with multiple skin lesions having been removed. There was no history of collagen vascular disease. She was found to have a large fixed breast mass and had modified radical mastectomy with postoperative irradiation. Pathologic examination showed an infiltrating ductal carcinoma with 15 of 21 nodes positive. The patient's digital ischemic symptoms worsened and gangrenous lesions of multiple fingers developed. Complete serologic evaluation including antinuclear antibody, rheumatoid factor, immunoglobulin electrophoresis, complement determination, cold agglutinins, and cryoglobulins were normal. Arteriography showed numerous digital artery occlusions with associated cold-induced vasospasm. Treatment with guanethidine gave some symptomatic relief. She had persistent digital ischemia for 2 years at which time she was found to have abdominal metastatic disease and was treated with hormonal therapy and chemotherapy. She died 7 months later of metastatic disease.

Case 2

A 49-year-old woman noted the onset of bilateral finger pain and cyanosis at the time of a modified radical mastectomy for infiltrating ductal carcinoma. No axillary lymph node involvement was present. The symptoms continued for 6 months, associated with progressive digital dysesthesia and fingertip gangrene. An arteriogram showed occlusion of most named palmar and digital arteries with associated vasospasm. The digital ischemia improved slightly after brachial artery injections of tolazoline and reserpine. Chest x-ray showed pulmonary metastases, and chemotherapy was begun. The digital ischemia persisted but did not worsen. Serologic tests showed a low-titer antinuclear antibody and nonspecific mild immunoglobulin elevations. Upper extremity nerve conduction showed diffuse neuropathic changes. The patient died 2 months after the initiation of chemotherapy. At necropsy she was found to have extensive metastatic carcinoma to the viscera. Pathologic examination of the radial artery and involved skin showed no evidence of inflammatory vasculitis, immune deposits, or thrombosis.

Case 3

This 75-year-old man with a life-long history of mild, stable Raynaud's syndrome was found to have chronic lymphocytic leukemia (CLL) in 1977. He received chemotherapy and was in remission. Five years later he had an abrupt onset of blanching of both hands and feet, followed in several days by gangrenous changes of most toes and fingers. These lesions persisted despite treatment with antibiotics, corticosteroids, and pentoxifylline. A skin biopsy specimen showed lymphocytic infiltration, believed to be secondary to his CLL. He was treated with Leukeran® for 6 months and the digital lesions healed. Four months later ischemic finger lesions again developed. Evaluation revealed an exacerbation of the leukemia, with a leukocyte count of 120,000/μL and gangrene of multiple fingertips. Digit plethysmography showed decreased pulsatile flow to the affected digits. The only abnormal laboratory finding was a small amount of plasma cryofibrinogen. His evaluation is summarized in Tables 2 and 3. The digital lesions improved somewhat with the initiation of leukemia chemotherapy, but the patient died 3 weeks later of septic complications.

Case 4

A 63-year-old woman noted the precipitous onset of cold-induced tenderness and blanching of her fingers followed by cyanosis and rubor. Within 3 weeks, small ulcerations and gangrenous changes of the tips of the thumbs, index, and middle fingers of the right hand and the index and middle fingers of the left hand developed. Magnification hand angiography showed widespread palmar and digital arterial obstruction (Fig. 1). The abnormal findings of her evaluation are summarized in Table 3, and included a striking elevation of IgG to 2,800 mg/dL. Hematuria led to renal angiography, which revealed an avascular mass in the upper pole of the left kidney. A radical nephrectomy was done and the mass was found to be a sarcomatoid renal adenocarcinoma, with metastasis to hilar, periaortic, and mesenteric nodes. After operation the digital ischemia improved with healing of the lesions over the next 2 months, associated with a decrease of IgG to normal levels. She received a short course of chemotherapy. Over the next 3 years she continued to have Raynaud's attacks and recurrent digital ulcerations. She had no evidence of metastases at this time, although the carcinoembryonic antigen (CEA) remained elevated. She was treated medically for her Raynaud's syndrome. She returned 3 months later with a large epigastric mass and died soon thereafter of recurrent tumor.

Case 5

A 43-year-old man was found to have gastric adenocarcinoma with extension to regional nodes and hepatic metastases. He was treated with chemotherapy with 5-fluorouracil and developed lower extremity deep vein thrombosis. He was anticoagulated with heparin followed by warfarin. Six months later while therapeutically anticoagulated with warfarin, right axillary vein thrombosis developed followed by the rapid onset of hand ischemia progressing to gangrene of the right thumb, index, middle, and ring fingers. Digit plethysmography confirmed absent arterial flow in these four fingers with preservation of normal pulsatile flow in the fifth finger and normal palpable radial and ulnar pulses (Fig. 2). Ten days later despite heparin treatment, deep

TABLE 3. *Summary of Clinical Courses of Described Patients*

Case Number	1	2	3	4	5
Malignancy	Breast, infiltrating ductal	Breast, infiltrating ductal	Chronic lymphocytic leukemia	Renal adenocarcinoma	Gastric carcinoma
Metastases	15 of 21 axillary nodes, ovarian, iliac, mesenteric nodes	0 of 14 axillary nodes, pulmonary metastasis	Remission 1977–1982	Recurrent peritoneal nodes	Mediastinal and lymphatic metastases
Treatment	L MRM 1969 XRT 1969 Oophorectomy 1976 XRT/CTX 1976	R MRM 1983 CTX 1984	Chlorambucil CTX-1977 Chlorambucil 1982–1985 CTX 1985	L radical CTX 1974	Laparotomy, CTX
Smoking history	80 pack years	Moderate, none 1980	80 pack years, none since 1966	Unknown	>100 pack years
Associated diseases	Neurofibromatosis	None	None	None	None
Previous Raynaud's syndrome	11-year history cold-induced pain and cyanotic changes	None	Cold-induced pain and blanching since adolescence	None	None
Digital lesions	Ulcerations, cyanosis and gangrenous changes over multiple fingers (bilateral)	Dysesthesias and punctate ulcerations and several gangrenous areas over 7 fingertips	Purpura, ulcerations with gangrenous lesions over 19 fingers and toes	Ulcerations and gangrenous changes over 5 fingers (bilateral)	Gangrene of fingers and distal palm
Angiography	Multiple digital artery occlusions, marked vasoconstriction with ice immersion, relieved with reserpine	Bilateral radial artery occlusion with multiple digital artery occlusions; some improvement with tolazoline	Not done	Left hand multiple arterial irregularities with narrowing, no improvement with reserpine	Not done
Skin biopsy	Not done	No cutaneous vasculitis or inflammation (at autopsy)	1. Vasocentric lymphohistiocytic infiltrate 2. Discoid lupus V. chilblains	Mild leukocytoclastic angiitis	No arteritis, widespread venous and arterial thrombosis
Treatment of digital lesions	Good response to reserpine orally and intra-arterial	Some relief with intra-arterial reserpine/ tolazoline/ dextran IV; mild relief with nifedipine and prednisone	Initial relief with chlorambucil, local wound care and CTX with recurrence	Increased symptoms following initial slight relief with guanethidine and phenoxybenzamine with recurrence	Amputation
Outcome	Died with extensive metastases 1976	Died of septic complications of CTX for pulmonary metastasis 1984	Died of septic complications of CTX 1985	Died with recurrent tumor 1977	Died 2 months after diagnosis
Autopsy	Extensive abdominal metastases	Metastases to lung and liver, radial artery patent, no evidence of vasculitis	Not done	Not done	Not done
Outcome of digital lesions	Acrocyanosis and several ulcerations at time of death	Acrocyanosis, petechiae, and single gangrenous ulcer	Great improvement and healing of ulcerations	Painful red hands with minimal ulcerations	No new lesions

MRM = modified radical mastectomy.
XRT = radiation therapy.
CTX = chemotherapy.

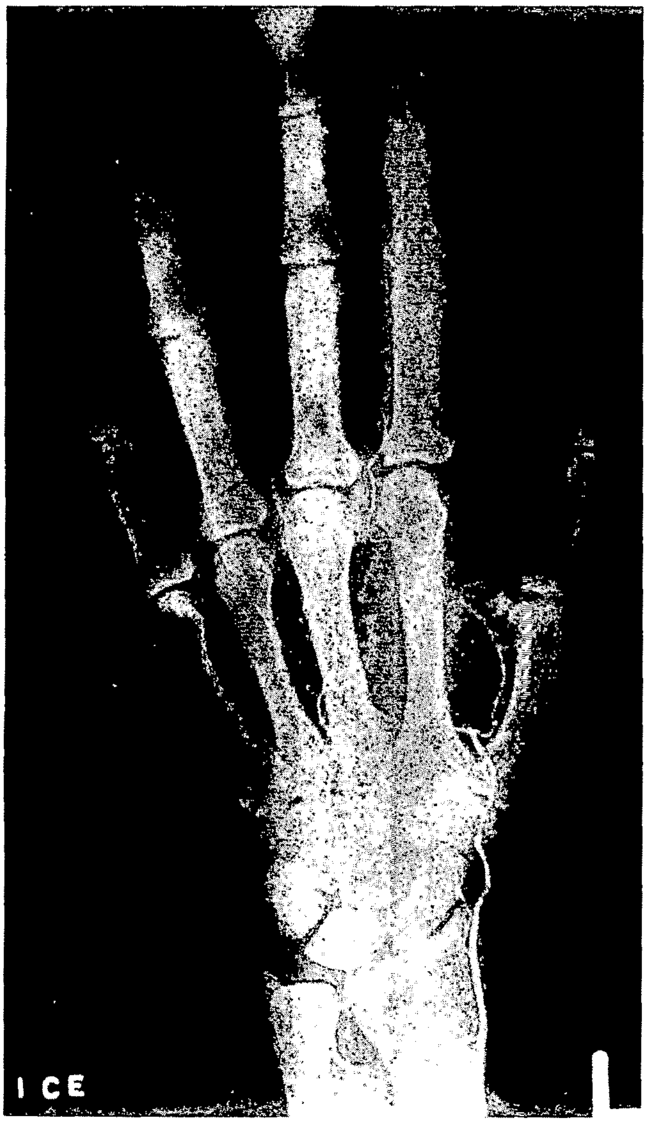

FIG. 1. Magnification hand arteriogram demonstrating widespread palmar and digital arterial obstruction (Case 4).

vein thrombosis recurred in the right leg. The patient died 2 months after limited hand amputation. Pathologic examination of the involved arteries showed no evidence of vasculitis. The details of the case histories are summarized in Table 3.

Discussion

Patients with episodic digital ischemic syndromes have been classically said to have Raynaud's disease if the condition exists alone and Raynaud's phenomenon if the ischemic symptoms exist in the presence of an associated disease process, frequently collagen vascular diseases.[20] Since neither of these terms describes a specific diagnosis, many authorities have abandoned them in favor of the term Raynaud's syndrome, used to describe the symptom complex of episodic digital ischemia in response to cold or emotional stimuli.[16] Fixed digital ischemic symptoms including gangrenous changes do not constitute Raynaud's syndrome as currently defined. Clearly, however, patients with severe digital ischemia may also have episodic symptoms that are properly termed Raynaud's syndrome. The patients described in this report all reported symptoms of Raynaud's syndrome accompanying their severe digital ischemia, and in two of the patients (Cases 1 and 3) these symptoms preceded the development of severe digital ischemia by years. The relationship between fixed digital arterial obstruction and Raynaud's syndrome has been described previously.[16]

Patients with Raynaud's syndrome may be conveniently divided into two groups, which we have termed spastic and obstructive with the differential point being the presence of fixed obstruction to flow in the palmar and digital arteries. Patients with spastic Raynaud's syndrome have symptoms as a result of an exaggerated vasospastic response to cold or emotional stimuli. Patients with obstructive Raynaud's syndrome have symptoms

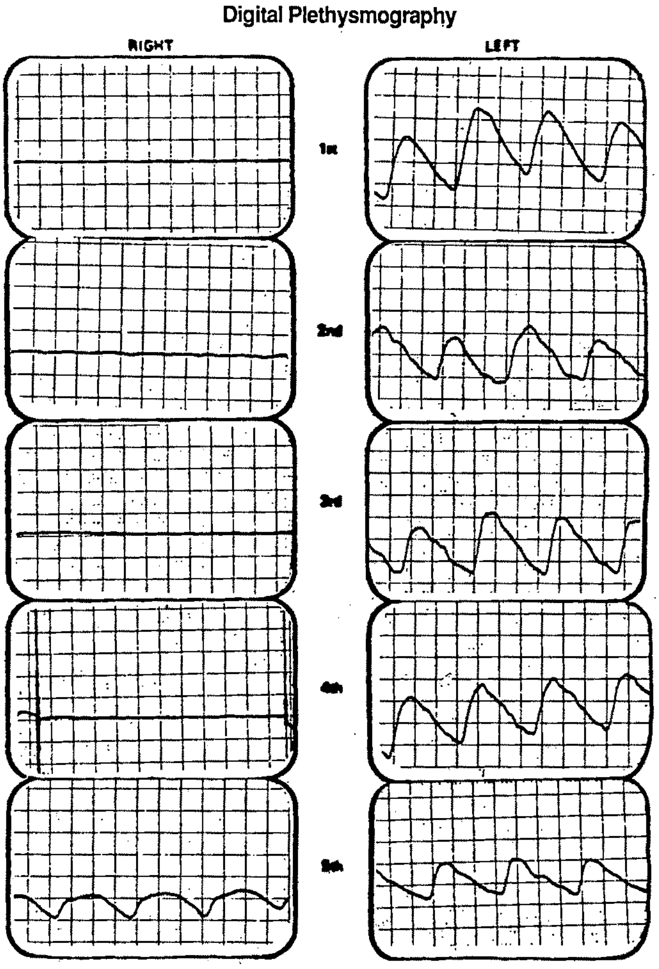

FIG. 2. Digital plethysmography demonstrating absence of pulsatile flow in right hand fingers 1–4 with normal pulsatile flow in left hand fingers (Case 5).

from digital artery closure caused by a normal vasoconstrictive response acting on an obstructed vessel.[21] Although spastic Raynaud's symptoms may be symptomatically severe, it has never in our experience caused digital gangrene. The latter has occurred only in the presence of diffuse palmar and digital arterial fixed obstructive disease.[17] The five patients with digital gangrene described in this report all had extensive fixed arterial obstructive disease in the hand and finger arteries as demonstrated by arteriography in three patients and digital plethysmography in the remainder. Three patients had a history of Raynaud's syndrome before the development of digital gangrene, and each patient had moderate improvement of ischemic symptoms after intra-arterial injection of vasodilators. Spastic Raynaud's syndrome preceding by years the development of fixed arterial obstruction and digital gangrene has been repeatedly noted by us and by others.[16,17,22]

Previous observers have postulated multiple mechanisms to explain the digital vasospasm and the digital artery obstruction producing digital ischemic symptoms in association with malignancy. Vasospasm has been attributed to sympathetic hyperactivity and to arteritis. Arterial obstruction has been attributed to arteritis, to hyperviscosity caused by elevated levels of a variety of serum proteins or of the formed elements of the blood, and to hypercoagulability associated with malignancy.

The earliest reports of digital ischemia associated with malignancy hypothesized vasospasm caused by metastatic tumor invasion of sympathetic nerves. Bennett and Poulton described in 1928 the case of a 61-year-old man with an occult gastric carcinoma who died during a cervical sympathectomy for relief of digital ischemic pain.[23] In 1963, Nielson and Petri reported a 77-year-old woman with bilateral digital gangrene and occult colon cancer with metastases to the cervical sympathetic chain and stellate ganglion.[24] None of the five patients described in this report had metastases detected to the sympathetic nerves to the upper extremity. The existence of bilaterally symmetrical symptoms in four of our five patients and in 22 of the 23 patients listed in Table 1 likewise mitigates against a local infiltrative process as the cause of this syndrome.

Arteritis of diverse etiologies has been clearly associated with digital artery vasospasm, as well as with digital artery obstruction producing finger ischemia and finger gangrene.[16,17,25] Several of the existing reports of tumor-associated digital ischemia have noted changes consistent with arteritis in the affected vessels, occasionally in association with circulating immune complexes.[26] The cause of the arteritis is unknown but may be related to tumor antigen–antibody complexes with subsequent complement activation in contact with the arterial wall.

Viscosity abnormalities have also been proposed as a mechanism of ischemia. An increase in blood viscosity may result from an increase in numbers of circulating blood cells as was noted by Hild and Myers who reported a case of ischemic necrosis of the fingertips, which they attributed to a severely elevated whole blood viscosity (Oswald viscosity: 7.1) in a patient with chronic granulocytic leukemia.[11] This mechanism appears to have resulted in digital ischemia in Case 3 in this series, in whom the granulocyte count was elevated to 120,000/μL at the time of severe symptoms. Hyperviscosity may also be caused by an increase in circulating blood proteins as was described by Domz and Chapman who related the 1961 case of a 56-year-old woman with adenocarcinoma of the lung who had elevated cryoglobulin levels and "pseudo-Raynaud's disease" progressing to gangrene. Tumor resection and concommitant decrease in circulating cryoglobulin level was associated with healing of the digital lesions and resolution of pain. Cryoglobulins were postulated to produce localized thrombosis and eventual infarction by precipitating prothrombin and accessory clotting factors.[27]

Hyperviscosity caused by cryoglobulinemia and arteritis may coexist.[28] In Case 4 described in this report, cryoglobulinemia was present in association with severely elevated IgG levels during the period of maximal digital ischemia. In this case the ischemia resolved and ulcerative lesions healed after resection of a sarcomatoid renal adenocarcinoma. Elevated gamma-globulin level, IgG immunofluorescence of tumor cells, and electron-dense deposits lining the endothelium of the tumor microvasculature were seen, suggesting the presence of immune complex deposition in vessel walls. Moore and Cupps in their review of the neurologic complications of vasculitis postulate immune complex deposition as the cause of both hypersensitivity vasculitis and systemic necrotizing vasculitis.[8] They cite the isolation of soluble immune complexes in experimental models, microscopic demonstration of immunologically mediated vascular destruction, and resolution of findings with immunosuppressants as justification for their conclusions.

Hypercoagulability in the absence of arteritis or hyperviscosity has been detected in 50–90% of patients with malignant tumors, especially those with metastases.[29,30] In as many as 15% of these patients, thrombotic events may be clinically apparent.[31] Case 5 described in this report had widespread venous and arterial thrombosis that progressed rapidly despite anticoagulant therapy. The relative resistance to treatment of this form of hypercoagulability has been well described.[32]

The fixed digital artery obstruction in these patients appeared to be caused by hyperviscosity in two patients. Arteritis was documented by pathologic findings and presumably caused the obstruction in two additional patients. In the final patient, diffuse digital artery obstruction resulted from thrombotic occlusion caused by hypercoagulability.

Four of the five patients described in this report had considerable symptomatic improvement after treatment directed at their primary neoplasms, emphasizing the ability of the hands and fingers to recover from severe ischemia, presumably through the development of collateral arterial channels.[17] Although antitumor therapy is of primary importance in treatment of these patients, the administration of vasodilators, currently calcium channel blockers, may result in moderate symptomatic improvement in those patients with an underlying vasospastic component in addition to the fixed arterial obstruction.

Digital gangrene in association with malignancy, although uncommon, is not rare and is being recognized with increasing frequency. The judicious application of angiography and plethysmography, serologic testing, and biopsy should permit accurate definition of which mechanism(s) of ischemia is (are) most important in the individual patient and permit selection of optimal therapy.

Gastric Transposition for Esophageal Replacement in Children

LEWIS SPITZ, PH.D., F.R.C.S., EDWARD KIELY, F.R.C.S.I., F.R.C.S., and TONY SPARNON, F.R.A.C.S.

Esophageal replacement by total gastric transposition was performed on 34 infants (32 with esophageal atresia) in the 5.5-year period from January 1981 to June 1986. There were three deaths (9%), two occurring in the early postoperative period, with the third occurring 1 year after surgery from persistent chronic respiratory problems. Fourteen infants had a totally uncomplicated course and have not required further admissions. Thirteen infants had early postoperative problems including six with delayed gastric emptying, four with anastomotic strictures requiring dilatation, and two with radiologic anastomotic leaks. Four late complications consisted of two adhesion intestinal obstructions, a perforation related to a jejunal feeding tube, and a child in whom malabsorption subsequently developed. An excellent result has been obtained in 24 infants, four doing well with only minor problems with feeding, and two are fair experiencing persisting difficulties. These results compare favorably with a large previous experience in colon interposition.

From the Department of Paediatric Surgery, Hospital for Sick Children, London, England

ESOPHAGEAL RECONSTRUCTIVE SURGERY presents a continuing challenge to the pediatric surgeon. The decision to replace the esophagus is always difficult due to the technical problems and major postoperative complications that may be associated with the substitution procedures. Various methods of esophageal substitution have been attempted, using either vascularized colon or jejunal interposition, gastric tubes, total gastric transposition, or free revascularized intestinal grafts to restore intestinal continuity.[1]

The significant morbidity associated with a large experience in colonic interposition at this hospital prompted a change in approach to evaluate the technique of total gastric transposition.[2] The utilization of stomach to restore continuity to the alimentary tract has been used successfully in adults for many years[3] with small reports of its use in children also being encouraging.[4,5]

This paper presents a review of the first 34 cases of transhiatal gastric transposition *via* either the posterior mediastinum or posterior thorax that have been performed at the Hospital for Sick Children in London in the 5.5-year period from January 1981 to June 1986.

Materials and Methods

Esophageal atresia was the primary condition in 32 infants with 18 having an associated tracheoesophageal fistula. In 27 infants a long gap prevented an initial primary anastomosis, whereas in five infants the initial anastomosis had disrupted and had to be abandoned. Two infants had severe esophageal damage, one from an extensive reflux stricture and the other from prolonged unrecognized foreign body impaction (Table 1).

The age at operation ranged from 7 days to 9 years with 23 of the 34 children 12 months old or less (Table 2).

Thirty-three associated congenital anomalies were identified in 13 of the 32 infants with esophageal atresia (Table 3).

Previous Surgery

Nine of the 27 infants with long gap esophageal atresia had had an initial attempt at delayed primary anastomosis. In one infant a gastric perforation developed, one infant had repeated cyanotic episodes related to upper pouch bougienage, severe aspiration penumonia developed in three infants, and in four cases the plan was abandoned as the gap did not significantly decrease after a delay of at least 60 days.

Large gap + proximal TEF	3
Large gap + distal TEF	10
Failed primary anastomosis	5
Extensive reflux stricture	1
Extensive damage from prolonged foreign body impaction	1
Total	34

TEF = tracheoesophageal fistula.

Fourteen children had previous major esophageal reconstructive procedures that failed, including eight failed colon interpositions with six being referred from other institutions for esophageal reconstruction. The two children with strictures secondary to reflux and prolonged foreign body impaction, respectively, had such extensive esophageal damage that local resection and reanastomosis were not possible.

Surgical Techniques

The operative procedure consisted of either a transhiatal gastric transposition *via* the posterior mediastinum[4] without a thoracotomy in 16 infants (Fig. 1) or a thoracoabdominal gastric transposition *via* the posterior thorax in 18 children. This included the eight previously failed colon interpositions as excision of the failed colons was a hazardous procedure, especially at the thoracic inlet and root of the neck where the recurrent laryngeal nerve must be carefully identified and preserved. A thoracotomy was also considered necessary in the children with extensive esophageal strictures and some of the failed primary anastomoses where extensive scarring from the leak necessitated careful dissection to remove the esophagus.

All except one child had a gastric outlet drainage procedure with 20 children having a pyloroplasty and 13 children having a pyloromyotomy. All patients had a large calibre (12-gauge) nasogastric tube inserted to prevent postoperative gastric distension. A fine-bore jejunal feeding tube was inserted to provide enteral nutrition before oral feeding was established.

After operation, 25 of 34 infants were electively ventilated.

Results

There were three deaths (9% mortality rate). All occurred in children with chronic respiratory problems from previous failed reconstructive surgery. Two children had cardiac arrests within 48 hours of surgery. The first occurred in a 2.5-year-old boy with long gap esophageal atresia in whom delayed primary anastomosis failed on two occasions. He had had a tracheostomy for a laryngeal cleft and required ventilatory support for prolonged periods. The second occurred in a 1.5-year-old girl with esophageal atresia and tracheoesophageal fistula. Her initial primary anastomosis disrupted and a subsequent colon interposition failed, leaving her with severe respiratory problems.

There was one late death in a 3-year-old boy. His birth weight was 1010 g, and an attempted delayed primary anastomosis failed. He required a tracheostomy for severe aspiration pneumonia and plication of an eventuated diaphragm at 6 months of age. His chronic respiratory problems progressed and he died 1 year after a successful gastric transposition.

Fourteen children have had an uncomplicated recovery and have never required readmission for further problems. Seventeen children had one or more postoperative complications. The most frequent problem occurring in ten children involved difficulty establishing oral feeds. In six children this was due to dealyed gastric emptying. Four children responded to oral metoclopramide, whereas in two children the gastric drainage procedure required revision. In four children the feeding problems were related to an esophagogastric anastomotic stricture that resolved after dilatation. Two minor anastomotic leaks were identified on contrast radiology, which was routinely performed 7–10 days after operation. In three children respiratory distress developed after operation. In two children this was due to inefficient nasogastric tube decompression allowing the stomach to become grossly distended, compromising the ventilation. Both children rapidly responded to maneuvers to improve nasogastric drainage. In the third child, respiratory distress was due to a hemothorax from bleeding initiated in the neck during the posterior mediastinal tunnel dissection. There were four late complications. One child required a laparotomy for peritonitis from a perforation due to the feeding jejunal tube. In two children adhesion intestinal obstruction developed requiring laparotomy, and a fourth child had diarrhea with malabsorption.

After the respiratory problems experienced earlier in the series a policy of elective postoperative mechanical ventilation was adopted in the subsequent 25 infants with between 1 and 30 days of ventilatory support (mean: 4.2 days) being required. The length of hospitalization ranged from 16 to 350 days (mean: 45 days), although 18 of the 31 survivors were discharged within 30 days of surgery. The period of follow-up is from 1 month to 5.5 years (mean: 3 years).

An excellent result has been obtained in 25 children who are entirely asymptomatic and manage a normal diet. Four children are doing well with occasional minor disturbances or dysphagia. Two children have had a fair result in that although they can feed orally, they have persistent problems related to either their tracheostomies or other associated abnormalities. Although these two children have required long periods of hospitalization, they have developed normally and should eventually have a successful outcome.

Six of 23 children in whom it has been at least one year since surgery remain below the third percentile for both height and weight.

Discussion

Numerous operative procedures have been described for esophageal reconstruction in infants born with esophageal atresia. They basically involve either esophageal anastomosis with[6–10] or without elongation techniques[11,12] or abandoning the esophagus and replacing it with various substitutes.[13–17]

Esophageal preservation using delayed primary anastomotic techniques has gained acceptance for long gap esophageal atresia. This method, however, often requires many weeks of preoperative specialized nursing care with the constant threat of aspiration pneumonia developing while awaiting growth of the esophageal ends. Nine children in this series were referred for esophageal substitution having had failed attempts at delayed primary anastomosis. A significant morbidity is also associated with the subsequent procedure with reports of anastomotic leaks complicating 30–60%, anastomotic strictures in 40–75%, gastroesophageal reflux in 60%, and abnormal esophageal motility in over 70%.[18,19] In addition, the mortality rate is as high as 25–40%.[7,10,18] These results have led us to agree with other surgeons who conclude that even though anatomic repair can be achieved in nearly all patients, some would be better served by staged esophageal replacement because the prolonged attempts to elongate the esophagus may be hazardous.[19,20]

children.[21] It was also the approach used at this hospital until 1981 when a change was made to total gastric transposition. A comparison of 112 children who had colonic replacement of the esophagus in this hospital in the 30 years before 1981 and 34 children who had gastric transposition in the subsequent 5.5 years is summarized in Table 4.

The change to gastric transposition has resulted in a slightly lower mortality and a substantial reduction in cervical anastomotic leakage (6% *vs.* 48%) and stricture (12% *vs.* 30%). No anastomosis required revision and the strictures responded to dilatation. There were no instances of the gastric transposition failing or undergoing necrosis. Gastrointestinal bleeding, reflux, and aspiration have not been a problem. Fourteen children had a trouble-free postoperative course and no further problems have developed during the period of follow-up. The outcome for the survivors of gastric transposition also compares favorably with 81% having an excellent result against 56% for colonic interposition.

Difficulty in re-establishing oral feeds was the most common complication. The usual cause was a temporary delay in gastric emptying, although two cases in which it persisted required revision of the drainage procedure. We consider it important to perform a pyloromyotomy or a formal pyloroplasty in addition to suturing the antrum to the diaphragmatic hiatus to maintain the pylorus within the abdomen to prevent this occurrence. In another two children, a total lack of interest in oral feeding resulted in a considerable delay in their discharge. Both had been poor "sham feeders" before operation. Considerable efforts are made to ensure that all infants and parents are coping with "sham feeding" after the initial cervical esophagostomy to prevent this problem. The routine placement of a jejunal feeding tube was of great assistance to the nutritional maintenance of the children with postoperative feeding difficulties. Oral feeding can then be reintroduced as tolerated with supplementary jejunal feeds given at night.

Sixteen children did not require a thoracotomy. The distal esophagus was dissected out of the posterior mediastinum through the esophageal hiatus and a posterior mediastinal tunnel created by blunt dissection *via* the cervical incision above and through the hiatus below. A thoracotomy was considered necessary to remove a previously failed colon interposition and was preferred in cases with extensive scarring after failed primary anastomosis. The two groups of patients who had gastric transposition with or without thoracotomy were not strictly comparable because the former group tended to have had previous major surgery, whereas the latter group comprised infants with a relatively uneventful previous course. The advantages of avoiding a thoracotomy included a reduced period of postoperative ventilatory support, a lower incidence of respiratory complications, and a shorter length of hospitalization. In addition, by confining the stomach to the posterior mediastinum, the theoretical pulmonary compression caused by postprandial gastric distension is avoided (Table 5).

The period of follow-up in this series is short but almost 70% of the children who are at least 1 year post-surgery are thriving with heights and weights within the normal centiles.

Results of Esophagogastrectomy for Carcinoma in Cirrhotic Patients

A Series of 23 Consecutive Patients

FRANCOIS FEKETE, M.D., JACQUES BELGHITI, M.D., DANIEL CHERQUI, M.D., FRANCOIS LANGONNET, M.D., and BRICE GAYET, M.D.

Esophagogastrectomy for carcinoma of the esophagus or cardia has been performed in 23 patients with histologically proven hepatic cirrhosis. All but two patients were classified as Child's class A and all but three had a prothrombin time over 60% of normal values. Twenty-two esophagogastrostomies were performed through a separate abdominal and right thoracic approach in 15 patients, a left thoracoabdominal approach in five patients, and without thoracotomy in two patients. One patient had a colon interposition. Six patients died after operation (26%) as a result of anastomotic leakage in two patients, hepatorenal in three patients and portal thrombosis in one patient. The type of procedure did not influence mortality. The most common postoperative complication was the development of ascites (65%), and when associated with hepatorenal syndrome there was a significant mortality ($p < 0.05$). Sepsis was present in the terminal stages of all nonsurvivors. A prothrombin time less than or equal to 60% of normal values was the only significant preoperative predictive factor of mortality, with none of the three patients surviving below this level ($p < 0.05$). It is concluded that the presence of cirrhosis is not a contraindication to esophagogastrectomy for carcinoma when curative resection can be undertaken. Hepatic reserve is the determinant factor of operative prognosis. Operative risk is acceptable if patients are classified as Child's class A and prothrombin time is over 60% of normal values. Operation should be delayed when acute alcoholic hepatitis is present. Intraoperative discovery of cirrhosis is not a contraindication to resection where the above criteria are met. This strict selection allows one to anticipate a lower mortality rate.

ESOPHAGOGASTRECTOMY PROVIDES the best prospect of long-term survival[1-4] in patients with esophageal carcinoma. Patients with cirrhosis may not be considered for surgical resection because of the high mortality and morbidity rates of gastrointestinal surgery reported in such patients.[5-8] However, with the advances in surgical treatment of esophageal carcinoma, and the lower associated mortality and morbidity,[1-3,9] some patients with cirrhosis may be candidates for surgical resection. The purpose of this study is to report our experience of esophagogastrectomy in patients with cirrhosis, and through the analysis of the data, we propose selection criteria for sugical intervention in this high-risk group of patients.

From the Department of Surgery, University Paris VII, Hopital Beaujon, Clichy, France

Materials and Methods

The charts of all consecutive patients with an association between carcinoma of the esophagus or cardia and cirrhosis treated in the Department of Digestive Surgery of Hopital Beaujon between January 1979 and May 1986, were retrospectively reviewed. Only those patients who had an esophagogastrectomy will be further discussed. Data concerning the history, diagnosis, and staging of both the tumor and the cirrhosis were listed for each patient. Preoperative data listed included serum levels of bilirubin, alkaline phosphatase, transaminases, and albumin. Prothrombin time was expressed as a percentage of normal values. Child's original classification[10] and prothrombin time were used to asses the severity of liver dysfunction. All patients had proven hepatic cirrhosis from preoperative and/or intraopertive liver biopsy. Pathology reports were reviewed to confirm cirrhosis and to assess the presence of stigmata of alcoholic hepatitis graded from absent to severe.[11] The location, histologic type and stage of the esophageal tumor were listed. Intraoperative data were collected including surgical procedure, operative duration and transfusion requirements. Postoperative mortality and morbidity were listed. Documented complications included: anastomotic leakage, pulmonary failure, ascites, hepatic fail-

Submitted for publication: December 24, 1986.

ure, and sepsis. Objective criteria were established defining each complication as follows: anastomotic leakage was radiologically documented by water soluble contrast swallow on postoperative day 7, or earlier in the presence of clinical symptoms of leakage; pulmonary failure was documented by abnormal chest roentgenogram showing penumonia or atelectasis, and/or the use of ventilator assistance for 4 days or more, in the absence of other major complication; ascites was documented by an increase of weight and abdominal circumference or issue of transsudative liquid through the drains; high flow ascites with renal failure defined hepatorenal syndrome; hepatic failure was defined by the association of prothrombin time below 60% of normal and a serum bilirubin level over 2 mg/dL; sepsis was documented by fever and positive cultures of ascites, sputum, blood, or urine. Length of hospitalization and survival were studied.

Operative mortality was statistically studied as a function of pre-intra-, and postoperative data by the Fisher's exact test for qualitative data and Student's t-test for quantitative data. Survival was studied by the Kaplan-Meier method.

Results

Patients

From January 1979 to May 1986, 718 patients with esophageal carcinoma were referred to our department. Hepatic cirrhosis was present in 48 patients (6.6%). Twenty-five patients were not operated on because of advanced tumors or cirrhosis. Twenty-three patients (48%) were operated on and had an esophagogastrectomy. There were 21 men and two women, aged 42–75 years (mean: 58 years).

Esophageal Tumors

Three patients had a cardioesophageal adenocarcinoma. Twenty patients had a squamous cell carcinoma: four were located on the lower third, 14 were located on the middle third, and two were located on the upper third of the esophagus. Tumors were considered to be suitable for resection on the absence of malignant spread judged on chest roentgenogram, tracheobronchoscopy, ultrasonography, computerized tomography, and isotopic bone scanning.

Cirrhosis

All patients were alcoholics and had histologically proven hepatic cirrhosis. A diagnosis of cirrhosis was made during operation in four patients. Two patients had previously had gastrointestinal bleeding from esophageal varices. In the remainder, diagnosis of cirrhosis was made during the staging of the esophageal carcinoma. Two patients were classified as class B in the Child's classification because of low albumin level (3 g%) in one patient and high bilirubin level (3 mg%) in the other; the other 21 patients were classified as class A. Three patients had a prothrombin time at 60% or less than normal values. Nine patients had normal hepatic tests. All patients were in good general condition.

Surgical Technique

All patients had an esophagogastrectomy, including 22 esophagogastric anastomoses and one colon interposition in a patient who had had a previous gastrectomy for peptic ulcer. The esophageal anastomoses were all made with an EEA or ILS stapling device. There were 19 intrathoracic anastomoses and four cervical anastomoses. Patients were classified into three groups according to the procedure used. Group 1 includes 16 patients who had esophagogastrectomy through a separate abdominal and right thoracic approach; there were 14 intrathoracic esophagogastrostomies and two cervical anastomoses through an additionnal incision. Group 2 includes five patients who had esophagogastrectomy through a single left thoracoabdominal approach. Group 3 includes two patients who had extrathoracic blunt esophagogastrectomy through an abdominal and cervical approach. Two thoracic drains were placed after all thoracotomies. All patients had abdominal drainage. Small-caliber suction drains were used. An intraoperative wedge liver biopsy was made in all patients. Mean duration and transfusion requirements in group 1 patients were 6.4 ± 1.1 hours and 2.7 ± 1.4 units, respectively; four patients died. The values were 4.2 ± 1.1 hours, 4.2 ± 0.2 hours, 1.2 ± 1.4 units, and 1.5 ± 1.5 units in groups 2 and 3, respectively. Two patients from group 2 and none from group 3 died. Operations in group 1 were longer and required more transfusions than the other groups ($p < 0.05$), but mortality was not significantly different.

Operative Mortality and Complications (Tables 1 and 2)

All patients remained in an intensive care unit for at least 8 days, with a minimum 12 hours of artificial ventilation. Postoperative care included water and sodium restriction, infusions of albumin and fresh-frozen plasma, diuretic and antibiotic therapy. Four patients had an uncomplicated postoperative course. Nineteen patients (87%) had 53 postoperative complications, and of these six died (26%). Causes of postoperative deaths were anastomotic leakage in two patients, hepatorenal syndrome in three patients, and mesentericoportal thrombosis with resultant intestinal infarction in one patient. Anastomotic leakage occurred in three patients (13%). One patient died after early disruption of the

TABLE 1. *Complications and Their Relationship with Mortality*

Complication	No. of Patients (%)	Mortality if Complication Present (%)

* $p < 0.05$ by Fisher's exact test.

anastomosis. Two patients had small anastomotic leaks, visible on routine contrast examination, but one patient subsequently died of an empyema, whereas the other patient healed on antibiotic therapy and parenteral nutrition. The most common complication was the development of postoperative ascites. It was observed in 15 patients (65%) and was associated with five deaths (33%). Fourteen of the 15 patients with ascites (93%) had a pleural effusion similar to ascitic fluid, and its evolution paralleled that of the ascites. Mean ascitic flow estimated on drain loss was 1450 mL/24 hours (500–3000 mL). Maximum ascitic flow was observed during the 5 days after operation and progressively decreased. Four patients had persistant ascites over 2 weeks. Hepatorenal syndrome developed in three patients and they died ($p < 0.05$); they all had an ascitic flow over 2000 mL/24 hours. Among the four patients with persistant ascites, ascitic leak occurred in three patients after removal of the drains; one had an infected ascites. Sepsis was observed in 10 patients and was associated with six deaths ($p < 0.05$). Two patients had positive ascitic cultures and died, four patients had pleural positive cultures and three died, four patients had positive sputum cultures and two died, two patients had positive blood cultures and one died, and five patients had positive urine cultures and three died.

Relationship between Preoperative Status and Mortality (Table 3)

Nine patients had normal hepatic tests; none of them died. Among the 14 other patients with abnormal values, six (42%) died. The only factor that significantly influenced operative mortality was a preopertive prothrombin time at 60% or less of normal values, with none of the three patients surviving below this level ($p < 0.05$). Hepatorenal syndrome developed in these three patients.

Outcome

Mean duration of hospitalization in survivors was 25.9 ± 12.5 days. No adjuvant therapy was used. One patient had several recurrences of ascites and encephalopathy with no sign of recurrent malignancy; the other patients recovered preoperative liver function. One patient with postoperative recurrent nerve paralysis died of aspiration pneumonia 8 months after surgery. Among the 16 surviving patients nine are alive and free of disease at between 5 and 77 months; seven died of cancer with a mean survival of 17 months. The actuarial survival rate is 72% at 1 year and 27% at 3 years.

Discussion

Esophagogastrectomy for carcinoma in cirrhotic patients has been mentioned only occasionally in the literature.[3,9,12] It is well established that gastrointestinal surgery in nonbleeding cirrhotic patients carries a high risk of mortality and morbidity. Mortality rates of 20–30% have been reported.[5,6] In this study we present a series of 23 consecutive esophagogastrectomies for carcinoma in an homogeneous group of cirrhotic patients with a 26% mortality rate. This rate is much higher than the 1.5–10% mortality rate reported for esophagogastric resection in noncirrhotic patients,[1–3,9] but our results compare favorably with those reported for more minor abdominal procedures in cirrhotic patients.[7,8] Our results indicate a 6.6% prevalence of alcoholic cirrhosis in patients with esophageal carcinoma, which has not been previously reported.

In this series, several types of esophagogastrectomies have been used. Operative mortality was not significantly influenced by the type of procedure, although operations with a separate abdominal and thoracic approach (group 1) were longer and required more blood transfusions. Where tumor was located on the lower third of the esophagus, a left thoracoabdominal ap-

TABLE 2. *Operative Mortality*

Patient #	Age	Child's Class	Pr (%)	AAH	Procedure	Cause of Death
1	62	B	100	+	Group 2	Anastomotic leak, day 4
2	69	A	83	−	Group 1	Blind fistula, day 33
3	63	A	76	−	Group 2	Portal thrombosis, day 23
4	42	A	60	−	Group 1	Hepatorenal syndrome, day 33
5	57	A	57	−	Group 1	Hepatorenal syndrome, day 23
6	49	A	58	+	Group 1	Hepatorenal syndrome, day 16

Pr (%) = prothrombin time in percentage of normal values.
AAH = acute alcoholic hepatitis.
+/− = present/absent.
See text for explanation of groups 1 and 2.

proach was used (group 3) to provide a better exposure of the esophagogastric junction and the splenic hilus. In middle-third tumors we have used a separate abdominal and right thoracic approach because of the necessity of a supra-aortic anastomosis. Two extrathoracic blunt esophagectomies (group 3) were peformed with a low intraoperative blood loss for a lower and an upper third growth, respectively. The favorable outcome in our two patients contrasts with the experience of Baker and Schechter[12] who reported two deaths in these cirrhotic patients who had extrathoracic esophagectomy. In contrast to other reports,[5,6] we did not find any correlation between mortality and intraoperative blood loss, which was estimated on transfusion requirements. This is probably explained by the fact that no massive intraoperative hemorrhage occurred. Cautious dissection and hemostasis are important. Thus, we cannot recommend one type of esophagogastrectomy in these patients; the choice must depend on the location of the growth and not on the presence of cirrhosis.

Mortality and morbidity after esophagogastrectomy is usually related to anastomotic leakage and pulmonary failure.[1,3,9,13] In this series, no patient died of pulmonary failure, and the rate of anastomotic leakage is not dramatically higher than in noncirrhotic patients.[9,13]

Four of the six deaths and most of the complications were directly related to cirrhosis. Ascites occurred in 65% of the patients in our series. It is a common complication after laparotomy in cirrhotic patients.[5,14] In one patient, ascites was due to a mesentericoportal thrombosis, but in 14 patients it was a primary complication directly related to the operation. The high frequency of postoperative ascites in our series could be explained by the interruption of the peri- and intraesophageal collateral circulation and by extensive lymphatic dissection.[14] Development of postoperative ascites gives rise to concern in these patients because it may expose them to the following specific risks: leakage of ascites through drain sites or operative wound with a risk of infection of ascites,[5] wound dehiscence, diaphragmatic compression, and metabolic disorders, including hyponatremia and renal failure favored by drain loss and diuretic therapy. This latter complication is important since high flow ascites with renal failure (hepatorenal syndrome) was associated with a significantly higher mortality. Prevention of postoperative ascites is difficult, but it is best done by water and sodium restriction and careful prescription of diuretics. When it develops, ascites should be evacuated to prevent parietal and respiratory complications. The two available methods are repeated paracentesis or abdominal drainage. Abdominal drainage is usually avoided when postoperative ascites is anticipated because of the risks of ascitic leak and infection. However, in previous reports, abdominal drainage after celiotomy in cirrhotic patients has not been associated with a higher mortality rate.[5] In this series, the 15 patients in whom postoperative ascites developed had drainage with only three leaks after the drains were removed and one ascites infection. We recommend one-way suction tubes, which should be removed only after ascites has been controlled. Drain loss must be compensated by albumin and fresh-frozen plasma and clinical and biological parameters closely monitored to detect and correct metabolic disorders. A pleural effusion was almost constant in the patients with ascites; it must be considered as a manifestation of ascites due to the peritoneopleural communication created by the operation. It represents another argument for abdominal drainage. Its managment is the same as that of ascites.

TABLE 3. *Relationship between Preoperative Status and Mortality*

Variable	No. of Patients (%)	Mortality if Variable Present (%)
Child's class B	2 (8.6)	1 (50)
Pr < 60%*	3 (13)	3 (100)
AAH present	5 (21)	3 (60)
Normal hepatic tests	9 (39)	0 (0)
Intraoperative discovery of cirrhosis	4 (17)	1 (25)

* $p < 0.05$ by Fisher's exact test.
Pr < 60% = prothrombin time 60% or less of normal values.
AAH = acute alcoholic hepatitis.

Postoperative hepatic failure, as defined above, was not a significant cause of mortality. However, our criteria can be criticized since modifications in bilirubin level and prothrombin time can results from other causes in the postoperative period such as blood transfusions, anesthetic agents, and disseminated intravascular coagulation. A postoperative increase in bilirubin level and decrease in prothrombin time were associated with death only in the patients in whom hepatorenal syndrome developed; thus, the latter syndrome seems to be the most specific stigmata of postoperative liver failure.

Sepsis was a major problem in the postoperative course of our patients and was present in all nonsurvivors, but in all of them, it followed on from a previous complication. It is best prevented by a meticulous postoperative care, and major antibiotherapy seems justified. Recent data suggest that broad-spectrum cephalosporins are the antibiotics of choice.[15]

Several recent reports, such as those by Garrisson et al.[5] and Doberneck et al.,[6] have studied operative risk of abdominal procedures in nonbleeding cirrhotic patients. They all confirmed that the main preoperative predictive factor of mortality was the degree of hepatocellular insufficiency, best reflected by the Child's classification and a decrease in prothrombin time. This is also true for the Sugiura operation[16] which shows some similarity with esophagogastrectomy. It would appear that cirrhotic patients with an esophageal carcinoma must be part of the best risk class to be candidates for surgical resection. In this series, all but two patients were classified as Child's class A, and the only significant preoperative predictor of mortality was a prothrombin time less than or equal to 60% of normal values. Three patients had a prothrombin time of 60% or less; they all had development of hepatorenal syndrome and died. Two patients were classified as Child's class B and one died. In retrospect, these five patients probably should not have been operated on. A high probability of resectability is also mandatory before proposing elective surgical exploration for esophageal carcinoma in patients with cirrhosis. Thus, strict preoperative selection of the patients can improve the results; none of the six consecutive patients operated on in the last 2 years died. It is interesting to note that, although this is not significant, intraoperative discovery of the cirrhosis and normal preoperative hepatic tests were associated with a lower mortality rate (1/4 and 0/9, respectively). Patients in whom cirrhosis is discovered during operation usually have an infraclinical cirrhosis and fulfill the above criteria of operability. Thus, intraoperative discovery of cirrhosis is no contraindication to resection.

Another factor that can alter hepatic function is the presence of acute alcoholic hepatitis (AAH). Whether AAH carries a higher risk for surgery or not has been well studied for shunt procedures[11,17]; it remains a matter of argument. It seems that quantitative statement of AAH is important. In this series no patient had severe AAH, but five had mild histologic signs of AAH with a few Mallory bodies and slight degree of necrosis; none had normal hepatic tests and three died. Although these observations were not statiscally significant, we believe that AAH must be considered a temporary contraindication. Therefore, we suggest that the presence of AAH should be assessed by a preoperative liver biopsy in patients with abnormal hepatic tests.

One of our patients died of postoperative mesentericoportal thrombosis with intestinal infarction. Mesentericoportal thrombosis is not an uncommon complication in cirrhosis[18,19]; it is favored by stasis in the mesentericoportal bed due to portal hypertension. It has been reported by Sugiura as a lethal complication of his operation.[15]

No postoperative gastrointestinal bleeding was observed. This can be explained by the fact that esophagogastrectomy is the most complete devascularization, with clearance of esophagogastric varices, similar to that aimed by the Suguira-type procedures.[20]

This study shows that major surgery in good-risk patients with cirrhosis does not definitely impair hepatic function in the surviving patients. Among the surviving patients of this study, all but one recovered preoperative hepatic function. Their survival compares with that of noncirrhotic patients in whom curative resection can be attained.[1] This is probably a result of a strict preoperative staging.[1]

CLASSIFIED AD SECTION

Classified advertising is available in **ANNALS OF SURGERY** for those recruiting personnel or interested in obtaining positions. Display space also is available for those desiring greater visibility or more space for their message.

Classified ad copy, like other advertising copy, will be reviewed for approval prior to publication.

Classified Rates: $9.00 per line or fraction of line. The average line will be 40 characters.

Box Numbers: Replies may be directed via Box # to J.B. Lippincott Company, at an extra charge per insertion of $6.50 to cover handling costs in forwarding such replies to the advertiser.

How to Order: Send typewritten text copy for the ad with remittance in full to:

ANNALS OF SURGERY
c/o J.B. Lippincott Company
Attn: Dorothy Glover
East Washington Square
Philadelphia, Pa. 19105
(215) 238-4215

Deadline: Copy received by the 15th of month will run in the second following month's issue, e.g. November 15th for January issue. Ads received after the 15th will run in the next available issue.

PRIVATE PRACTICE: Wanted general or thoracic surgeon, BC/BE, to join same, vascular training desired. Metropolitan city, S.C. with University affiliation. Please respond with curriculum vitae and references: **Box ANN 7B, J.B. Lippincott Company, East Washington Square, Philadelphia, Pa. 19105.**

SOUTHEASTERN NEW MEXICO: We are seeking a board certified/board eligible general surgeon interested in a lucrative career move with a first year guaranteed salary of $90,000. This up-to-date private practice has a service area population of approximately 30,000. For additional information, please send current CV to **Linda Smith, Occupational Health Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri 64111; or call 800-821-5147 or 816-561-2105.**

The community of ARTESIA, NEW MEXICO is seeking a Board Certified or Eligible **GENERAL SURGEON** to establish a private practice. Fully-equipped office with established referral patterns available for purchase. Community-based financial assistance may be available to the right individual. Artesia is a community of 14,000 located in Southeast New Mexico. A great place to raise a family—peaceful community with year-round recreation and excellent weather. Fully equipped, 38-bed new hospital. Please submit CV to: **Bill Norris, Southwest Community Health Services, P.O. Box 26666, Albuquerque, NM 87125-6666; or, call 1-800-545-4030, Ext. 8300.**

PLASTIC & RECONSTRUCTIVE SURGEON: 200 member multi-specialty group seeks BC/BE specialist; large primary, secondary, and tertiary practice with substantial referrals; adjacent to 500 bed hospital with superior intensive care unit; free-standing ambulatory surgery center; affiliated with medical school, part time faculty appointments available; located in upper midwest tri-college community of 130,000; 35 minutes from clean lake region; will pay travel expenses for physician and spouse to travel. Send CV in confidence to **Charles B. Anderson, M.D., P.O. Box 2067, Fargo, ND 58123.**

PEDIATRIC SURGEON: 200+ member multispecialty group seeks BC/BE specialist to join colleague; large primary, secondary, and tertiary practice with substantial referrals; adjacent to 500 bed hospital with superior intensive care units; Pediatric and high-risk nursery, NACHRI designated Children's Hospital; air ambulance & helicopter; affiliated with medical school, part time faculty appointments available; located in upper midwest tri-college community of 130,000; 35 minutes from clean lake region. Send CV in confidence to **Charles B. Anderson, M.D., P.O. Box 2067, Fargo, ND 58123.**

Energetic young board certified or board eligible general surgeon to fill position as full time assistant in a growing five man cardiac surgery practice in desirable Northern California location. Excellent salary and benefits. Please respond with curriculum vitae. **Box ANN 7C, J.B. Lippincott Company, East Washington Square, Philadelphia, Pa. 19105.**

GENERAL SURGEON For full time faculty position with training and principal interest in the field of nutrition. Gastrointestinal and/or encodrine surgery. Department of surgery, medical college of Ohio. Address inquiries to **Neil R. Thomford, M.D., Chairman, Department of Surgery, Medical College of Ohio, C.S., 10008, Toledo, OH 43699.** The medical college of Ohio is an equal opportunity employer.

House physician with 2 or more years of formal training in surgery wanted for a 275 bed hospital. Excellent fringes. Hospital will cover malpractice insurance. **Call George Kellas, M.D. (304) 242-6889.**

The only parenteral

q12h dosage means cost-effectiveness

- ☐ Cost per day less than Tagamet* Injection q6h**
- ☐ May result in fewer I.V. set-up charges, less nursing time, less pharmacy time, lower administrative costs

Efficacy

Prompt, persistent, predictable pH control for many patients

Tolerability

Excellent tolerability profile—even in critical care patients

Dosing intervals may need to be prolonged or dosage reduced in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine. PEPCID® I.V. (Famotidine, MSD) is contraindicated in patients who are hypersensitive to any component of this medication. The adverse reactions reported for PEPCID Tablets may also occur with PEPCID I.V. In addition, transient irritation at the injection site has been observed with PEPCID I.V.

H_2 antagonist with q12h dosage

Indicated in some hospitalized patients with pathological hypersecretory conditions or intractable ulcers or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.

The recommended dosage is 20 mg q12h.

INJECTION, 10 mg/mL

q12h **Pepcid® IV**

(Famotidine|MSD)

For a Brief Summary of Prescribing Information, please see the following page.

TABLETS
Pepcid®
(Famotidine|MSD)
20 mg and 40 mg

ORAL SUSPENSION
Pepcid®
(Famotidine for
Oral Suspension|MSD)
40 mg per 5 mL

INJECTION
Pepcid® IV
(Famotidine|MSD)
10 mg per mL

Contraindications: Hypersensitivity to any component.

Precautions: *General:* Symptomatic response to therapy does not preclude the presence of gastric malignancy.

Patients with Severe Renal Insufficiency: Longer intervals between doses or lower doses may be needed in patients with severe renal insufficiency (creatinine clearance < 10 mL/min) to adjust for the longer elimination half-life of famotidine (see Clinical Pharmacology and Dosage and Administration sections of Prescribing Information).

Information for Patients: The oral suspension should be shaken vigorously for 5-10 seconds prior to each use, and unused constituted oral suspension should be discarded after 30 days.

Drug Interactions: No drug interactions have been identified. Compounds tested in man include warfarin, theophylline, phenytoin, diazepam, aminopyrine, and antipyrine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In rats and mice given oral doses up to approximately 2500 times the recommended human dose for active duodenal ulcer, there was no evidence of carcinogenic potential, no evidence of a mutagenic effect, and fertility and reproductive performance were not affected.

Pregnancy: *Pregnancy Category B*—There are no adequate or well-controlled studies in pregnant women. Use during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether famotidine is secreted into human milk; however, it is secreted into the milk of lactating rats. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: No dosage adjustment is required based on age but may be necessary in severe renal impairment (see Clinical Pharmacology section of Prescribing Information).

Adverse Reactions: The adverse reactions listed below have been reported during domestic and international clinical trials in approximately 2500 patients. In the placebo-controlled clinical trials, the incidence of adverse experiences with PEPCID Tablets, 40 mg at bedtime, was similar to that with placebo.

Incidence Greater than 1%: The following adverse reactions have been reported to occur in more than 1% of patients on therapy with PEPCID in controlled clinical trials and may be causally related to the drug: headache (4.7%), dizziness (1.3%), constipation (1.2%), and diarrhea (1.7%).

Causal Relationship Unknown: The following other adverse reactions have been reported in clinical trials. While a causal relationship could not be established for these infrequently reported events, causality cannot be excluded. *Body as a Whole*—Fever, asthenia, fatigue. *Cardiovascular*—Palpitations. *Gastrointestinal*—Nausea, vomiting, abdominal discomfort, anorexia, dry mouth, liver enzyme abnormalities. *Hematologic*—Thrombocytopenia. *Hypersensitivity*—Orbital edema, conjunctival injection. *Musculoskeletal*—Musculoskeletal pain, arthralgia. *Nervous System/Psychiatric*—Paresthesias; grand mal seizures (single report); psychic disturbances including depression, anxiety, decreased libido, hallucinations (single report); insomnia; somnolence. *Respiratory*—Bronchospasm. *Skin*—Alopecia, acne, pruritus, rash, dry skin, flushing. *Special Senses*—Tinnitus, taste disorder.

The adverse reactions reported for PEPCID Tablets may also occur with PEPCID Oral Suspension or PEPCID I.V.; in addition, transient irritation at the injection site has been observed with PEPCID I.V.

Management of Overdosage: There is no experience to date with deliberate overdosage. Up to 640 mg/day have been given to patients with pathological hypersecretory conditions with no serious adverse effects. In the event of overdosage, treatment should be symptomatic and supportive. Unabsorbed material should be removed from the gastrointestinal tract, the patient should be monitored, and supportive therapy should be employed.

Dosage and Administration: *Duodenal Ulcer:* The recommended adult oral dosage for active duodenal ulcer is 40 mg h.s.; most patients heal within 4 weeks, and it is rarely necessary to use the full dosage for longer than 6 to 8 weeks. A regimen of 20 mg b.i.d. is also effective. For maintenance therapy, the recommended oral dosage is 20 mg h.s.

Pathological Hypersecretory Conditions (e.g., Zollinger-Ellison Syndrome, Multiple Endocrine Adenomas): The dosage varies with the individual patient; the recommended adult oral starting dosage is 20 mg q6h, but some patients may require a higher starting dosage. Dosages should be adjusted to individual patient needs and continued as long as clinically indicated; up to 160 mg q6h have been administered to some patients with severe Zollinger-Ellison syndrome.

Oral Suspension: The Oral Suspension may be substituted for Tablets for those patients who cannot swallow tablets.

Directions for Preparing PEPCID Oral Suspension: Prepare suspension at time of dispensing. Slowly add 46 mL Purified Water. Shake vigorously for 5-10 seconds immediately after adding the water and immediately before use.

Stability of PEPCID Oral Suspension: Unused constituted oral suspension should be discarded after 30 days.

Intravenous Administration: In some hospitalized patients with pathological hypersecretory conditions or intractable ulcers, or in patients who are unable to take oral medication, the recommended intravenous dosage is 20 mg q12h. For preparation of solutions for injection or infusion and for compatible diluents, please see Prescribing Information. Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Concomitant Use of Antacids: Antacids may be given concomitantly if needed.

Dosage Adjustment for Patients with Severe Renal Insufficiency: In patients with severe renal insufficiency (creatinine clearance less than 10 mL/min), the elimination half-life of famotidine may exceed 20 hours, reaching approximately 24 hours in anuric patients. Although no relationship of adverse effects to high plasma levels has been established, to avoid excess accumulation of the drug, the dosage may be reduced to 20 mg h.s. or the dosing interval may be prolonged to 36 to 48 hours as indicated by the patient's clinical response.

How Supplied: Tablets, containing 20 mg or 40 mg famotidine, with hydroxypropyl cellulose, hydroxypropyl methylcellulose, iron oxides, magnesium stearate, microcrystalline cellulose, starch, talc, and titanium dioxide as inactive ingredients, in bottles of 30 and unit-dose packages of 100; Oral Suspension, containing per 5 mL after constitution with 46 mL Purified Water, 40 mg famotidine, with citric acid, flavors, microcrystalline cellulose and carboxymethylcellulose sodium, sucrose, and xanthan gum as inactive ingredients, and sodium benzoate 0.1%, sodium methylparaben 0.1%, and sodium propylparaben 0.02% added as preservatives, in bottles of 400 mg famotidine for constitution; Solution for intravenous injection, containing 10 mg famotidine per mL, with L-aspartic acid 4 mg, mannitol 20 mg, and water for injection q.s. 1 mL as inactive ingredients, and benzyl alcohol 0.9% added as preservative to the multidose vial, as 10x2-mL single-dose vials and as 4-mL vials.

Effects of Thymectomy in Myasthenia Gravis

ANGELOS E. PAPATESTAS, M.D., GABRIEL GENKINS, M.D., PETER KORNFELD, M.D., JAMES B. EISENKRAFT, M.D.,
RICHARD P. FAGERSTROM, PH.D., JASON POZNER, A.B., and ARTHUR H. AUFSES, JR., M.D.

Factors influencing onset of remission in myasthenia gravis were evaluated in 2062 patients, of whom 962 had had thymectomy. Multivariate analysis showed that appearance of early remissions among all patients was significantly and independently influenced by thymectomy, by milder disease, and by absence of coexisting thymomas. Patients with mild generalized symptoms treated with thymectomy reached remission more frequently, even when compared with those with ocular myasthenia treated without surgery. Short duration of disease before thymectomy in mild cases was another factor associated with earlier remissions. Mortality for all patients was significantly and independently influenced by severity of symptoms, age, associated thymomas, and failure to remove the thymus. Patients without thymectomy and with thymomas had, in addition, earlier onset of extrathymic neoplasms. Morbidity after the transcervical approach was minimal. This study demonstrates that early thymectomy by the transcervical approach, when technically feasible, has significant clinical advantages over the transthoracic approach and should be advocated for all patients with myasthenia gravis, including those with ocular disease.

From the Departments of Surgery, Medicine, Anesthesia, and Biostatistics of The Mount Sinai Medical Center and the Mount Sinai School of Medicine, New York, New York

THE ROLE OF THYMECTOMY in myasthenia gravis has not been fully investigated beyond confirming early empirical observations[1] that it is frequently followed by remission of symptoms of the disease. Reports of delayed remissions after thymectomy,[2,3] of decreases in associated extrathymic neoplasms,[4] and of the low morbidity with the transcervical approach[5] have provided additional indications for early surgical intervention, even in patients with mild generalized symptoms. As a result, thymectomy, which was previously used in a selected subgroup of patients,[6] is now performed in all patients with generalized disease.

Indications for the various treatment modalities have changed in recent years. Age, sex, severity of symptoms, lack of control of symptoms with medication, duration of disease, and presence of thymoma were used in earlier years as indicators for surgery.[6] The effect of these factors on the clinical course of the disease has not been adequately studied, even though they should be considered potential confounders when evaluating the results of treatment. It seemed appropriate, therefore, to perform multivariate analysis to identify factors that significantly influence the time intervals either from diagnosis or from thymectomy, to the onset of remission, the development of extrathymic tumors, and death.

The long-term results of the transcervical and transthoracic approaches were compared to determine whether the latter offers any clinical advantage, since in the existing controversy proponents of the sternal approach have advocated a "complete thymectomy" rather than demonstrating a clinical advantage from "radical thymectomy."[7-10] The immediate postoperative course of transcervical and transthoracic approaches was also evaluated.

Materials and Methods

The clinical course of 2062 patients with myasthenia gravis registered at our institution between 1951 and 1985, of whom 962 had had thymectomy, was evaluated to identify factors that influenced the onset of complete remission, the appearance of extrathymic neoplasms, and mortality.

The following factors were considered potential confounders in evaluating the interval from onset of disease, or from surgical treatment, to the end points of the study: age and sex of the patient, age at onset of symp-

TABLE 1. *Patients in the Study*

Treatment	No Thymectomy	Thymectomy All	Thymectomy Cervical	Thymectomy Thoracic
No thymoma	1048	788	651	137
Ocular/Mild/Severe	(297/401/350)	(3/472/313)	(3/432/216)	(0/40/97)
Thymoma	52	174	44	130
Ocular/Mild/Severe	(4/11/37)	(9/57/108)	(0/22/22)	(9/35/86)
Total	1100	962	695	267

toms, severity of disease at time of confirmation of diagnosis, presence of thymoma, age at thymectomy, time period and hospital where surgery was performed, surgical technique, operating surgeon, and duration of disease from onset to thymectomy. For the development of extrathymic tumors, only the first primary malignancy, occurring after the diagnosis of myasthenia gravis, was taken into consideration. Skin neoplasms other than melanomas were not included in the analysis.

In the multivariate analysis severity of disease was coded as: ocular; mild generalized, which included cases with Classes IA and IIA symptoms; or severe, which included cases with Classes IIB, III, and IV symptoms, using the Osserman classification.[11] Duration of disease before surgery was coded as either short, *i.e.*, less than 3 years, or long, which included patients operated on with a delay of 3 or more years after diagnosis. Surgical technique was coded as transcervical or transthoracic. The latter included median sternotomy (complete or partial), lateral intercostal thoracotomy, and parasternal mediastinotomy. One of us (AEP) performed 557 operations, of which 512 were for patients without associated thymoma, and results in this group were compared with those obtained by other surgeons. Patients followed at our institution but operated on in other hospitals were grouped in a separate category. Remissions and mortality were evaluated from the time of diagnosis in all patients and also from the time of surgery in those patients who had thymectomy. Since the proportion of patients in remission increases with time after thymectomy,[2] the analysis of patterns of remission was performed taking this factor into consideration.

Postoperative mortality, need for prolonged postoperative ventilatory assistance or for tracheostomy, and length of hospital stay were factors that were considered in evaluating the immediate postoperative course. The postoperative courses of patients operated on between 1973 and 1986 were evaluated separately from those of the preceding period, as the perioperative management of patients remains essentially unchanged since 1973. Adherence to a variety of postoperative treatment protocols in different years precluded an unbiased evaluation of the immediate postoperative course and complete information on the variables of interest was not available in all patients.

Follow-up information was obtained by patient examination or by questionnaire. Statistical analysis of onset of remission, mortality, and appearance of extrathymic neoplasms was performed using the Cox Proportional Hazards model[12] and the patterns of remissions and of mortality were plotted using the 1L program of the BMDP Statistical Software package (BMDP Statistical Software, Department of Biomathematics, University of California, Los Angeles, CA).[13] Associations between noncontinuous variables were evaluated using the chi-square test.

Results

Thymectomy and/or the transcervical approach were treatment methods not evenly distributed among subgroups of patients. There were significant variations in the proportions of patients with thymomas and/or severe symptoms both among the groups treated with or without surgery and within the subgroups defined by surgical technique. Thymomas were observed in 226 of 2062 patients (11%) with myasthenia gravis. Among patients who had thymectomy, the proportion was significantly higher compared with that of patients who were not operated on as 174 of the 963 patients who were operated on (18%) were found to have thymomas, compared with 52 of 1100 (5%) patients who were not operated on ($p = 0.0001$). Significant differences in the percentage of thymomas were also noted in relation to severity of disease. Among mild cases, 81 of 1254 patients (6%) had thymomas, whereas among those with severe symptoms 145 of 808 patients (18%) had associated thymic tumors ($p = 0.0001$). Only one third of patients without thymomas had severe symptoms compared with two thirds of those with associated thymomas. The majority of patients who had thymectomy (72%) were operated on *via* the transcervical approach but there was a significant difference in this proportion in relation to the presence of thymoma. Of 788 patients without thymoma, 651 (83%) had transcervical thymectomy compared with 44 of 174 patients (25%) with thymoma ($p = 0.0001$). Most patients who had the transcervical approach had milder disease compared with those operated on by one of the transthoracic approaches (Table 1). The majority of patients with ocular disease were not

treated by thymectomy. Remission and mortality varied significantly with severity of disease and presence of thymoma in both the operated and nonoperated groups of patients (Table 2). Overall, patients who had thymectomy had a higher proportion of remissions, lower mortality, and less frequent extrathymic neoplasms.

Severity of disease, presence of thymoma, and thymectomy were all factors that emerged from the multivariate analysis using the Cox Proportional Hazards model as significantly and independently influencing the interval from onset of disease to onset of remission. The most important factors contributing to an early onset of remission were milder forms of disease, thymectomy, and absence of thymoma with all three factors having a significant and independent influence (Table 3). Sex and age of the patient did not influence the results. The patterns of remission from time of diagnosis for patients with or without thymectomy and with or without thymoma are shown in Figure 1. The earliest remissions appear in patients without thymoma treated by thymectomy. Patients with thymomas who had operation, although they had considerable delay in onset of remissions, eventually had a higher proportion of remissions than patients without thymomas treated without surgery (Fig. 1).

The analysis was repeated in patients without thymoma after stratification according to severity of symptoms. A higher proportion of remissions was noted in those with mild disease treated by thymectomy. Patients who had progressed to severe symptoms before thymectomy had a similar pattern of remission as patients treated without thymectomy who had ocular or mild generalized symptoms. The group with the fewest remissions was that of patients who had progressed to severe symptoms but had not had thymectomy (Fig. 2). The duration of preoperative symptoms for patients who had thymectomy is shown in Table 4. It was noted that 25% of patients without thymoma had a duration of symptoms of more than 3 years by the time of thymectomy. Although 87% of thymomas were diagnosed and treated within 3 years of onset of symptoms among patients operated on in each of the subsequent periods, 21 of 218 patients (10%) were found to have thymomas (Table 4). Thymomas were found with increasing frequency in the older age group, particularly among patients with severe symptoms. The highest proportion (42%) was noted in patients over 50 years of age at the time of surgery, who had severe symptoms.

When remissions were evaluated for patients who had thymectomy, it became evident that the time from thymectomy to remission was significantly and independently influenced by the presence of thymoma, severity of disease, the surgical approach, and by the duration of preoperative symptoms. Patients without thymoma, those with milder symptoms, those who had had transcervical thymectomy, and those with short duration of disease (less than 3 years) showed earlier onset of remis-

sion (Table 5). Comparison of the patterns of remission from the time of surgery in patients with and without thymoma revealed that patients without thymoma and who were operated on by the transcervical approach had earlier remissions, and the advantage was sustained in the entire follow-up period (Fig. 3). No significant difference in the remission rate of patients with thymomas was noted in relation to surgical technique.

The pattern of remissions was evaluated separately for patients operated on by one of us (AEP) because inclusion of the variable "surgeon" in the multivariate analysis showed that this factor significantly influenced the results. Within the homogeneous group of patients without thymomas who were operated on by AEP, those who presented a combination of mild disease with short duration of symptoms had the earliest onset of remissions, whereas the other three groups showed delayed patterns (Fig. 4). The analysis was limited to the first 10 postoperative years because there were no patients with mild symptoms who were operated on within 3 years from onset of myasthenia, with a follow-up longer than 12 years. At 10 years after thymectomy, 67% of patients with short duration of symptoms and mild disease were in remission compared with 28% of those who had progressed to severe symptoms.

The interval from the time of diagnosis to death of the disease was influenced significantly and independently by the factors shown in Table 6. Those patients who

were older at diagnosis, with severe forms of the disease, and those with thymoma and without thymectomy had a shorter survival. The pattern of mortality in relation to presence of thymoma and surgical treatment is shown in Figure 5. Mortality after thymectomy was significantly influenced by four independent factors (Table 7). Those patients operated on *via* a transthoracic approach, those with more severe disease, with thymomas, and older at time of diagnosis had a higher mortality.

Evaluation of the development of extrathymic neoplasms revealed 131 patients in whom the first extrathymic neoplasms were diagnosed after the onset of myasthenia gravis, and 25 patients in whom neoplasms occurred after thymectomy. Of these, 89 occurred in patients who had not undergone thymectomy and 42 occurred among patients who were operated on (Table 2). Multivariate analysis showed that in addition to the age of the patient, there were three other significant and independent factors influencing the appearance of extrathymic tumors after the diagnosis of myasthenia gravis. Earlier appearance was noted in patients with thymoma, in those who did not have thymectomy, and those who had not reached remission (Table 8).

Comparison between the postoperative courses of patients who had transcervical and transthoracic thymectomy was made after stratification by the time in which the patients had thymectomy. The majority of operations in recent years were performed by the transcervical approach. Mortality was very low in patients without thymoma, and no postoperative deaths occurred after 1973. Patients who were operated on after 1973 also had a lower postoperative morbidity in that fewer patients required tracheostomy, prolonged intubation or ventilation, or extended hospital stay (Table 9). Approximately three of four patients without thymoma who had thymectomy required hospitalization for no longer than 5 days. Within the group of patients operated on after 1973, those who had transcervical thymectomy had a significantly higher proportion of short hospitalizations and fewer tracheostomies.

Discussion

The current study clearly demonstrates that thymectomy significantly influences the clinical course in patients with myasthenia gravis. Compared with nonsurgical treatment, thymectomy is followed by an earlier onset of remissions, lower mortality, and a delay in the appearance of extrathymic neoplasms. The multivariate analysis demonstrates that the presence of a thymoma, the severity of disease, and the age of the patient are factors that significantly influence the clinical course of the disease regardless of treatment and represent independent prognostic indicators. No meaningful evaluation of treatment modalities in myasthenia gravis is possible without taking into consideration the effect of these factors. This study also confirms that thymectomy has an advantage over nonsurgical treatments[14] and that the effects of thymectomy are delayed.[2,3]

The findings indicate that even patients treated by thymectomy show an increasing percentage of remissions with increasing time intervals after diagnosis. This observation confirms previous reports[15] of delayed remissions among patients with generalized disease who

were treated without surgery and does not support the previously held notion that spontaneous, or rather, nonsurgical remissions are limited to patients with ocular disease. It is obvious, therefore, that the pattern of delayed remissions, which had been demonstrated repeatedly in patients after thymectomy,[2,3,5,15] is evident in all subgroups. Results shown in Figure 2 seem to be similar to those of Oosterhuis[15] except for the ocular group, and his results suggest that overall the natural course of the disease is influenced by the same factors in both the Dutch series and ours. The difference noted in the ocular group between the two series may be associated with the less strict criteria used by Oosterhuis, who included patients with sporadic diplopia and ptosis when fatigued at the end of the day in the remission group.

From the observed differences in remission and/or in mortality, among patients treated with and without thymectomy, it appears that the role of thymectomy is to avert progression of the disease, decrease mortality, and accelerate the onset of remission.

The difficulty in evaluating the results of treatment

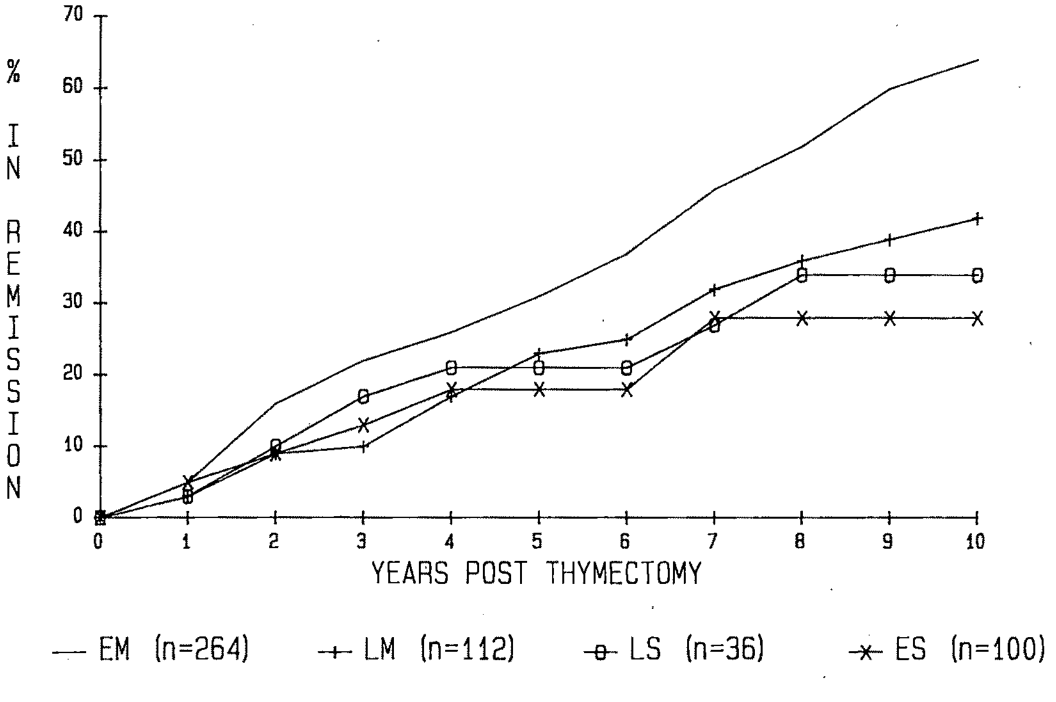

FIG. 4. Interval from thymectomy to remission in patients without thymoma operated on by AEP. EM: short duration and mild symptoms; LM: long duration and mild symptoms; LS: long duration and severe symptoms; TS: short duration and severe symptoms.

modalities without considering potential confounders is further complicated by the facts that thymomas occur more frequently in association with severe disease, are frequently undetected on routine roentgenograms, and may have been unrecognized in previous years when thymectomy was performed only in young patients in whom nonsurgical treatment had failed. The data in Table 4 indicate that approximately 10% of patients who had thymectomy more than 3 years after onset of myasthenia had thymomas and that these were more frequent than had been previously noted among older patients with severe symptoms. Although the adverse clinical course of patients with thymoma has been known for many years,[1,15] the independent impact of the severity of disease on the clinical course has not been previously appreciated.

The findings of our study (Fig. 2) lend support to Schumm's suggestion[16] that thymectomy is indicated in ocular cases. Since thymectomy stops progression of the disease, early intervention before the symptoms become generalized may be advisable. Thymectomy, particularly when performed *via* the transcervical approach, has minimal morbidity and is devoid of the risk of side effects from immunosuppressive drugs. The inability to determine the clinical course of the disease at the time of onset of symptoms[17] and the inability to exclude the presence of thymoma are additional indications for early intervention.

The current study also casts doubt on the validity of the earlier concepts that the sex of the patient influences therapeutic results and that patients over the age of 40 do not do well after thymectomy, as neither sex nor age entered the stepwise analysis when the interval to remission was analyzed (Tables 3 and 5). This confirms the results of our previous report that evaluated thymectomy in patients over the age of 40.[18]

TABLE 6. *Factors Influencing Mortality After Diagnosis in All Patients**

Thymectomy	0.0000	0.0000	5.2179

* Number of patients = 2062; number of patients who died = 391.

In recent years thymectomy has become recognized as an established therapeutic procedure,[14,19] and arguments as to whether thymectomy should be performed in myasthenia gravis have taken second place to the question of which is the appropriate surgical approach to the thymus. The focus of the controversy has been the feasibility of complete removal of the thymus *via* the transcervical approach rather than the advantage offered by the surgical approach in terms of superior long-term clinical results. Proponents of the transthoracic approaches and advocates of radical thymectomy, which includes removal of mediastinal fat through a combined transcervical and transthoracic approach, have failed to prove a relevant clinical advantage of these procedures over the transcervical approach.[10] Therefore, the argument that a more complete thymectomy can be achieved with the radical approach is a moot point if

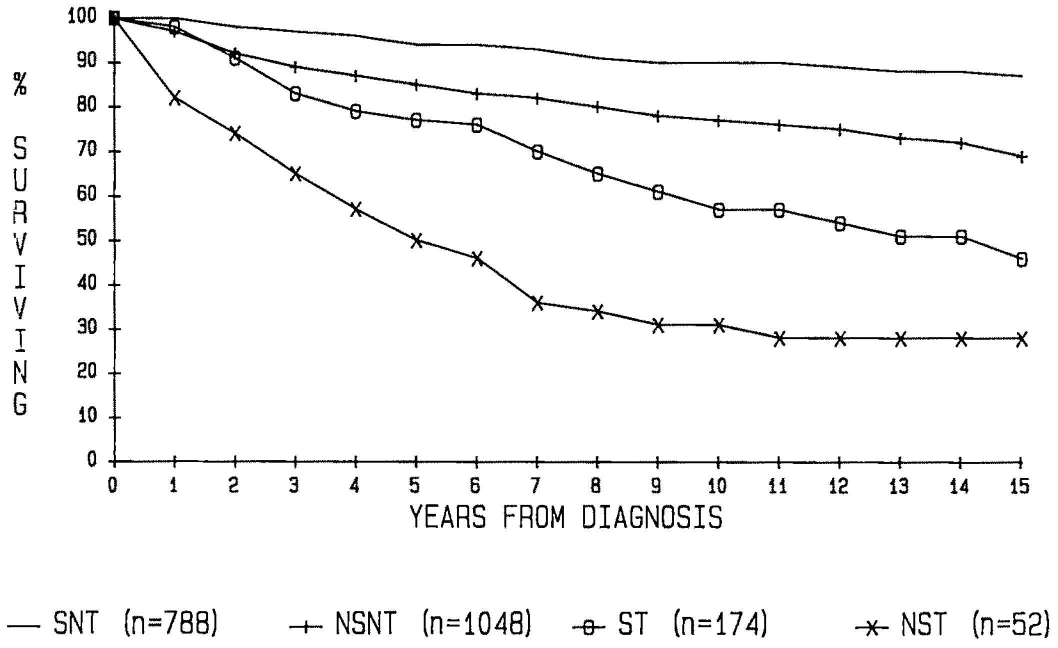

FIG. 5. Interval from diagnosis to death. SNT: thymectomy, no thymoma; NSNT: no thymectomy, no thymoma; ST: thymectomy, thymoma; NST: no thymectomy, thymoma.

TABLE 7. *Factors Influencing Mortality After Thymectomy**

Variable	Univariate p	Stepwise p	Coefficient/SE

* Number of patients = 962; number of patients who died = 139.

superior clinical results cannot be demonstrated after the use of this technique.

The current study, which addresses the question of whether surgical approach influences the clinical results, does not provide any evidence for advocating a transthoracic removal of the thymus. Indeed, even after considering the effect of independent confounders, a slight advantage of the transcervical approach persisted in terms of long-term results (Table 5). The highly significant advantage of the transcervical approach noted in the univariate analysis was not as significant in the stepwise analysis, indicating that most of it could be explained by the fact that the transcervical technique was used more frequently in patients without thymomas, in those with milder disease, and in those having a shorter duration of symptoms. It is clear that severity of disease and timing of operation affect the results more significantly than the approach, and that the best results were obtained in the group of patients who were treated with early intervention, before clinical progression of the disease. Two additional reports, from surgeons having a large experience with the transcervical approach, substantiate the advantage for early intervention.[8,20] Patients operated on by AEP had earlier onset of remission but this may also reflect a more complete follow-up as similar advantages were noted in patients operated on at our institution after 1973. In earlier years, asymptomatic patients were discharged from follow-up studies. Further analysis would be necessary to determine the cause for this advantage in these patients.

* Number of patients = 2062; number of neoplasms = 131.

† Neoplasms occurring in operated patients before thymectomy listed as occurring in patients without thymectomy.

The experimental findings indicating that the protective effect of thymectomy against neoplasms is superior in mice operated on by a technique that results in retention of thymic remnants, compared with a technique that is associated with a complete removal of the thymus,[21] add additional doubts as to the validity of advocating a radical approach to thymectomy. The thymus, which is considered to have an endocrine function, is embryologically derived from the same brachial pouches as the parathyroid, whereas abnormalities of thyroid function are frequent in myasthenic patients.[11] The endocrine mechanism in myasthenia was pointed out by Simpson.[22] If we extrapolate from the experience obtained with thyroid and parathyroid surgery, complete excision of the endocrine gland for hyperthyroidism or primary hyperparathyroidism is rarely indicated and sufficient control is obtained in the majority (approximately 90%) of cases even with a subtotal removal. It is therefore difficult to justify the persistent calls for radical thymectomy since there is neither clinical evidence of, nor scientific basis for, advocating such an approach. Most surgeons who have had experience with the transcervical approach[7–9] prefer it over the transsternal approach, and they agree that the long-term results are comparable to those obtained with the transthoracic approach. In addition, the immediate postoperative course is smoother as a result of the minimal operative trauma. Some of the proponents of the transcervical approach do not recommend it in patients with thymomas,[7] but those who have become familiar with the technique and have used it extensively[5,8,23] report removal of small thymomas, when technically feasible, through the neck incision. The results in Figure 3 indicate that there is no clinical disadvantage when thymomas are removed by the transcervical approach and therefore the alleged disadvantage of the transcervical approach in terms of exposure does not appear to have any clinical relevance.

Residual thymus, or regeneration of the gland after thymectomy, has been implicated in the failure of the procedure to result in remission in all cases. Because of the delayed clinical response after thymectomy, which is influenced by factors unrelated to treatment and surgical technique, it is difficult to identify patients who might benefit from re-exploration to remove residual thymic tissue. Indications for re-exploration in the 10–15% of patients who fail to respond to thymectomy should be based on clinical course or computerized tomographic (CT scan) findings. Re-exploration for residual or ectopic thymus may be indicated, regardless of the original approach, if a patient shows signs of progressive deterioration of symptoms after a prolonged and sustained improvement. Additional thymic tissue has been found in patients operated on originally by both transcervical and transsternal approaches.[24–26] In our series one of the six patients who had reached remission after thymectomy had a relapse of symptoms 5 years later,

* Data available in 585 patients.

† Data available in 105 consecutive patients operated on in 1983–1986.

had re-exploration, and residual thymus was removed. Relapse of symptoms after remission seems to be rare both in our experience and in other reports.[27] Whether the removal of residual tissue will benefit the patient is not clear as long-term follow-up information in these patients is not yet available. Blalock's original technique, as pointed out in the report of Mulder et al.,[27] was not a complete thymectomy, yet the patient derived a definite benefit.

The current study did not address the issue of specific mortality from myasthenia gravis because the cause of death was not always readily available from the records. It would be of interest to address this issue in future analyses, taking into consideration the possibility of increased mortality from associated extrathymic neoplasms in patients who had not had thymectomy.

Previous studies have suggested that there is an increased incidence of extrathymic neoplasia among myasthenic patients and that thymectomy is not followed by this increased incidence of extrathymic tumors.[4,28,29] The current study confirms that development of extrathymic neoplasms after the diagnosis of myasthenia gravis is significantly less frequent among those patients who had had thymectomy.

Thymectomy, particularly when performed by the transcervical approach, is evidently a safe procedure associated with minimal morbidity. Complete information on the immediate postoperative course was not available in all our patients. The available results (Table 9) indicate that in recent years (1983–1986), need for postoperative ventilation and frequency of tracheostomy have been decreasing.

Of 92 consecutive patients who had thymectomy from 1983 to 1985 and who were monitored in the postoperative period, only eight (8.7%) who had transcervical thymectomy required postoperative mechanical ventilation for more than 3 hours as we previously reported.[30] Other centers report that patients who have transsternal thymectomy require prolonged mechanical respiratory assistance far more frequently.[31–33] Routine tracheostomy used to be commonplace in previous years when the transsternal approach was used, and this accounts for the high proportion of tracheostomies shown in Figure 9 for the period preceding 1973. Even in more recent series of transsternal thymectomies, 30% of patients required mechanical ventilation for more than 3 days and 7% required tracheostomy.[33] In our series only 26 of the 588 patients (4%) who had transcervical thymectomy after 1973 required tracheostomy, whereas intubation beyond 0.5 hour after completion of surgery was required in only 10% (Table 9). Early extubation was also noted in other centers using the transcervical approach.[34] Although thymectomy through the neck was described as a procedure taking 15–20 minutes,[35] in our experience the operating time is rarely less than 20 minutes and is more frequently 60–90 minutes. The difference may be due to the fact that thymic hyperplasia is encountered in most myasthenic patients and this necessitates additional blunt dissection to achieve good visualization of the lower attachments of the thymic lobes. Longer operative time is also necessary when parasternal mediastinoscopy[36] is required for removal of small thymomas.

In today's budget-conscious environment it is difficult to justify the added cost of technical procedures that have disadvantages in terms of immediate morbidity and no advantage in terms of long-term clinical results. Considering both long- and short-term advantages as well as efficient use of health resources, it would seem that early surgical intervention, *via* the transcervical approach when technically feasible, represents the treatment of choice for patients with myasthenia gravis.

A Dose-responsive Model of Smoke Inhalation Injury

Severity-related Alteration in Cardiopulmonary Function

TAKESHI SHIMAZU, M.D., TETSUO YUKIOKA, M.D.,* GENE B. HUBBARD, D.V.M., M.S., PAULETTE C. LANGLINAIS, M.S., ARTHUR D. MASON, JR., M.D., and BASIL A. PRUITT, JR., M.D.

From the U.S. Army Institute of Surgical Research, Fort Sam Houston, San Antonio, Texas

The dose responsiveness of selected physiologic indices was studied in a sheep model of smoke inhalation injury. In this model, graded severity of injury was achieved by changing the contact time with smoke (defined by "unit"), whereas other variables were kept constant. Blood gas and cardiopulmonary indices were measured in 70 sheep, including 12 controls, either 24 or 72 hours after exposure to 3, 6, 9, 12, 15, or 18 units of smoke. A 12-unit dose of smoke was fatal within 72 hours and an 18-unit dose was fatal within 24 hours. The best correlation between smoke dose and response was observed in arterial oxygen tension 24 hours after exposure. At 24 hours, most of the cardiopulmonary indices showed significant change only after a 12-unit exposure. Although the exact shape of the dose-response curve could not be defined, sigmoid or curved linear shape was suggested, reflecting the progressive deterioration.

SMOKE INHALATION INJURY is one of the primary determinants of survival after major burns.[1] The significance of pulmonary injury due to smoke inhalation in burn patients was not widely realized until the 1970s, although antecedent work by Phillips had indicated the likelihood that such injury was of consequence.[2-4] In recent years early diagnosis of smoke inhalation and evaluation of its severity have achieved wide clinical interest, but even now the pathophysiologic mechanisms of the injury are not clear. Although several animal models have been developed to study such mechanisms, they have either been small animal models[5-8] or failed to permit control of severity.[9-12] We have developed a sheep model of smoke inhalation injury that is reproducible and dose-responsive.

Sheep are large enough to allow detailed physiologic monitoring and frequent blood sampling.[13-14] A technique for lung lymph cannulation has also been established for sheep.[15] In this model, dose responsiveness was assessed by changing the duration of smoke exposure to the lung while keeping other factors that influence severity unchanged. The severity of smoke inhalation injury is related to smoke temperature, chemical and physical composition of the smoke (gas, vapor, and particle), contact time (time exposed to smoke), and contact area (depth of breath). In the current system, the smoke was equilibrated at ambient temperature to exclude all possibility of thermal injury to the airway. The animals were exposed to a volume of smoke proportional to their body weight. The severity of injury in a spontaneously breathing animal is also influenced by hyperventilation in response to the carbon monoxide content of the smoke.[16] Spontaneously breathing animals with elongated nasal passages, with epiglottic closure, or with early bronchospasm may show further variability in severity of injury.[12] In this work, smoke exposure was done under general anesthesia using endotracheal intubation to avoid changes in the depth of breath that affect contact area. With respect to smoke

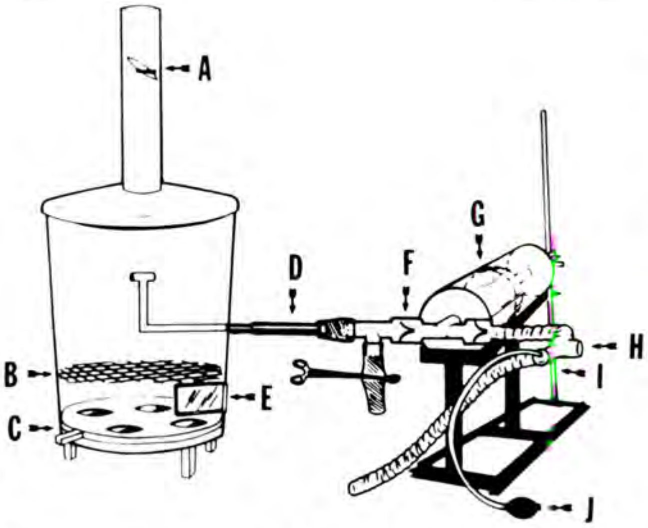

FIG. 1. Schematic presentation of smoke generator and smoke delivery system. Disposable underpads are burned in the smoke generator. Smoke is introduced through the copper pipe (D) to the volume-adjustable metal syringe (G). Either smoke or air is introduced into the pump by clamping the other rubber connection. Animals are intubated and connected to the outlet (H). Animals are insufflated with smoke when the exhalation valve (I) is closed manually by pressing the rubber bulb (J). (A) Damper; (B) Mesh; (C) Adjustable air inlet; (E) Window; (F) One-way valve.

composition, fluctuation of combustion was minimized by the relatively large size of the combustion chamber (32 gallons, 122 liters).

After smoke exposure, the sheep were extubated and allowed to breathe spontaneously to assess the natural history of smoke inhalation injury. Twenty-four or 72 hours after smoke inhalation, the sheep were reanesthetized, intubated, and catheterized for the measurement of pulmonary arterial and systemic arterial pressures. After a 2-hour stabilization period, cardiopulmonary indices were measured under anesthesia, using mechanical ventilation, a state that corresponds to the situation in patients in an intensive care unit setting.

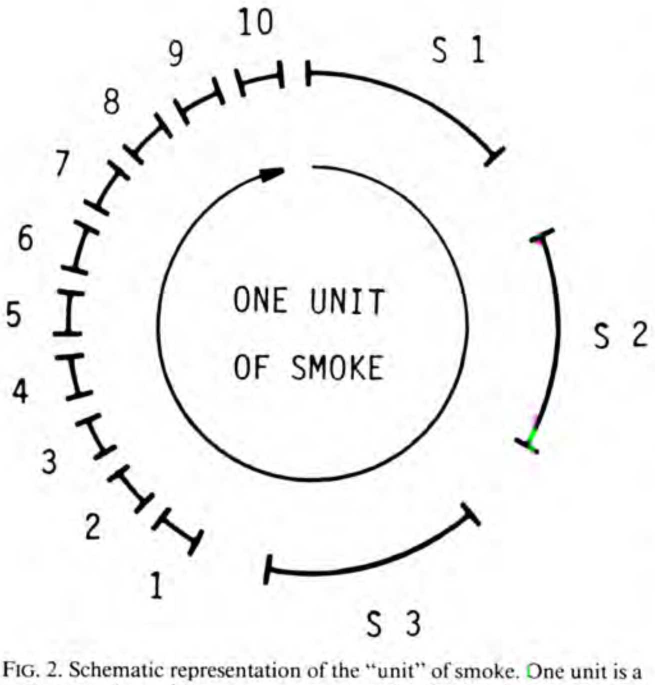

FIG. 2. Schematic representation of the "unit" of smoke. One unit is a cycle comprised of three exposures to smoke (S1–S3) followed by ten short ventilations with air. See text for details.

This report describes the dose dependence of alterations in cardiopulmonary function after smoke inhalation.

Materials and Methods

Animals

One- to two-year-old neutered male, commercially available, random source sheep weighing 30.8 ± 4.3 kg (mean ± SD) were used in this study. The animals were housed in covered outdoor runs, treated for parasites, and fed commercial chow and water *ad libitum*. Baseline complete blood counts, total proteins, and blood chemistries were done 3 weeks before experimental use. The animals were fasted for 24 hours before smoke exposure and experimental use. Twelve sheep were used as controls and 58 were exposed to smoke; 41 sheep were studied 24 hours after smoke exposure and 17 sheep were studied 72 hours after exposure. Immediately after smoke inhalation, the sheep were housed in climate-controlled facilities at 74–76 F (24–25 C) and a relative humidity of 40–50%.

Smoke Generation and Exposure

Smoke was produced by burning 10 disposable underpads (45 × 52.5 cm, 40 g each, Hosposable, Inc., Bound Brook, NJ) made of polyethylene, wood pulp, and nonwoven cellulose fabric. The smoke generator was a 32-gallon metal container equipped with an air inlet, a dampered chimney, a window, and smoke outlet (Fig. 1). The smoke passed through a copper pipe (30 × 1.6 cm) into a volume-adjustable metal syringe, which permitted insufflation of either smoke or air. The smoke reached ambient temperature during passage through the pipe and delivery system and contained 10–14% oxygen, 3–8% carbon dioxide, 0.7–2.2% carbon monoxide, and other combustion products (methane, ethylene, propylene, and acetaldehyde), but no cyanide.

The experimental sheep were individually exposed to 3, 6, 9, 12, 15, or 18 units of smoke. One unit of smoke consisted of three successive exposures to smoke with a tidal volume of 30 mL/kg and breath hold of 5 seconds followed by 10 successive ventilations with room air (Fig. 2). The time required per unit was about 50 seconds. Before smoke insufflation, the sheep were intubated, anesthetized with methohexital sodium (9 mg/kg, Brevital® Sodium, Eli Lilly and Company, Indianapolis, IN) and paralyzed with succinylcholine chloride (0.7 mg/kg). The sheep were extubated after smoke inhalation. Of the 41 sheep studied 24 hours after smoke exposure, six sheep were exposed to 3 units of smoke, eight sheep to 6 units, nine sheep to 9 units, seven sheep to 12 units, seven sheep to 15 units, and four sheep to 18 units. For the 72-hour studies, seven, six, and four sheep were exposed to 6, 9, and 12 units of smoke, respectively.

Monitoring

Sheep were studied 24 or 72 hours after smoke inhalation. On the day of measurement, arterial and central venous lines, a Swan-Ganz catheter (7F, American Edwards Laboratories, Irvine, CA), a lung water catheter (American Edwards Laboratories), and an esophageal balloon were inserted after general anesthesia and intubation. Anesthesia was induced with methohexital sodium (9 mg/kg) and maintained with alpha-chloralose (0.05 g/kg, Calbiochem®, La Jolla, CA) and the sheep were paralyzed with pancuronium bromide (0.03–0.04 mg/kg, Pavulon®, Organon Pharmaceuticals, West Orange, NJ). After the placement of catheters, the animals were positioned prone and artificially ventilated. A volume-limited ventilator (Bear 2™, Bear Medical Systems, Inc., Riverside, CA) with a tidal volume of 15 mL/kg was used at a respiratory rate of 12 per minute. Sigh ventilation with a tidal volume of 21 mL/kg was applied every 3 minutes to prevent atelectasis. Lactated Ringer's solution was continuously infused at a rate of 1 mL/kg per hour.

Central venous pressure and pulmonary artery pressure (PAP) were monitored with Statham P23Db transducers (Statham Instruments, Oxnard, CA) and systemic arterial pressure was monitored with a Hewlett-Packard 1290A quartz transducer (Hewlett-Packard Company, Waltham, MA). These pressures were recorded on a Hewlett-Packard four-channel recorder (Model 7754A). Respiratory indices were monitored with a pneumotachograph (Model 17212, Gould, Inc., The Netherlands) for flow rate and tidal volume and a differential transducer (MP-451, Validine Engineering Corporation, Northridge, CA) for transpulmonary pressure, with the pulmonary variables recorded on another Hewlett-Packard four-channel recorder (Model 7754A). Cardiac output was measured in triplicate by thermodilution technique (cardiac output computer, Model 9520A, American Edwards Laboratories) and lung water was measured by thermal-dye double indicator-dilution method (lung water computer, Model 9310, American Edwards Company). Blood gas analysis was performed using an IL 1303 pH/blood gas analyzer and an IL 282 CO-Oximeter (Instrumentation Laboratories, Inc., Lexington, MA). Cardiopulmonary indices and blood gas levels were measured every 30 minutes, and the values measured after 2 hours of stabilization were taken as representative values.

Necropsies were performed on all sheep dying spontaneously or sacrificed at the end of the experiments. A complete set of tissues was fixed in 10% neutral buffered formalin and processed by standard methods. The locations of the tissue sample collection sites were midtrachea, tracheal bifurcation, right and left proximal and distal bronchi, apical and diaphragmatic lobes, and any other morphologically significant foci.

Data are displayed as mean ± SE. Regression analysis by least-square technique was used to examine the linear relationship between physiologic variables and the number of units of smoke. Linear regression analyses included the control sheep unless otherwise indicated. Survival rate was analyzed by stepwise logistic regression. Multiple comparisons were done by one-way analysis of variance (Tukey studentized range method and the Student-Newman-Keuls multiple range test). Differences were considered significant at $p < 0.05$.[17]

Results

Sheep resumed spontaneous breathing soon after smoke exposure, and breathing was supported by an ambu-bag until they were extubated. The sheep usually started walking within 10 minutes after smoke exposure. Sheep exposed to smoke showed symptoms such as coughing, wheezing, and frothing beginning 4–6 hours after smoke exposure. All sheep in which physiologic measurements were made could breathe spontaneously and stand unassisted, although sheep exposed to 12 units or more showed distinct respiratory distress.

Sloughing of the airway epithelium occurred consistently in sheep exposed to smoke (Fig. 3). This pseudomembrane formation was typically seen in major airways and became progressively thicker in sheep exposed to higher doses of smoke. At autopsy, almost complete occlusion of the trachea was seen in sheep that died spontaneously 12 or more hours after exposure. Histologic changes of the airways included disruption, swelling, and loss of cilia (Fig. 4A). Increased numbers of inflammatory cells were common in the laminae propriae, respiratory mucosae, and airway lumina. Surface accumulation of mucocellular debris, often with obstruction, was associated with parenchymal congestion, edema, and atelectasis (Fig. 4B). These parenchymal changes were most prominent in the dependent areas of the lung.

Mortality at 24 and 72 hours is shown in Figure 5. Six units or less of smoke was not fatal by 72 hours, but 12-unit doses were fatal by 72 hours. Therefore, 15- or

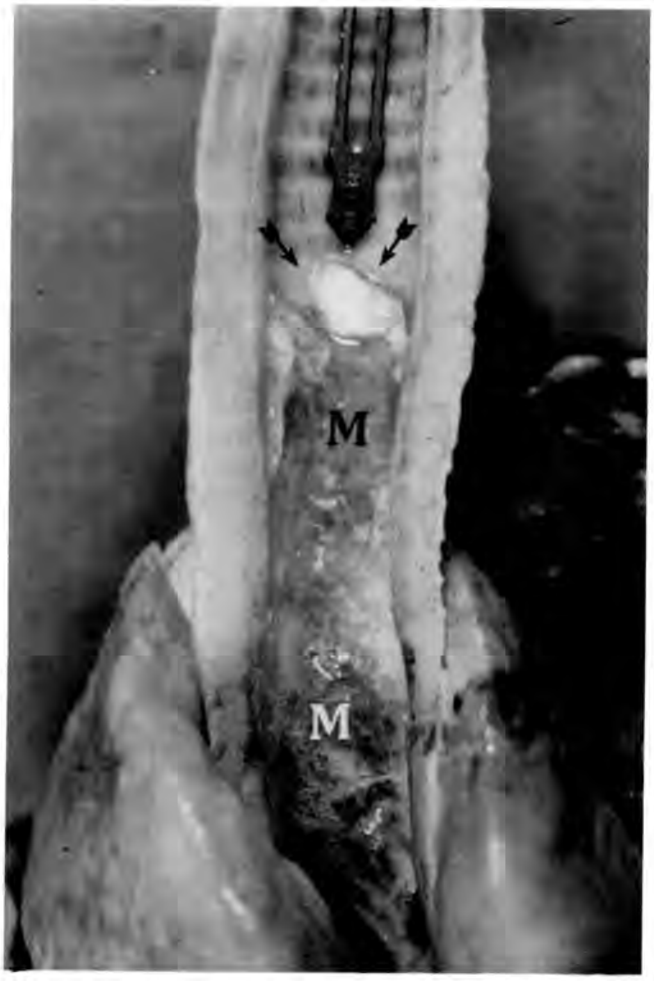

FIG. 3. Trachea of a sheep 24 hours after exposure to 9 units of smoke. This photo illustrates the formation of a pseudomembrane (M) in the trachea and bronchi. The membrane is separating from the underlying epithelium (arrows) and partially occludes the trachea and lower respiratory tract.

18-unit smoke exposures were not studied for survival or physiologic response at 72 hours. Eighteen-unit doses were fatal by 24 hours; one of the four sheep receiving an 18-unit dose died within 1 hour after exposure and three others died between 5 and 15 hours after exposure. Mortality at 24 hours was well predicted by the logistic model (mortality = exp(y)/(1 + exp(y)), where $y = 0.535x - 7.865$ and x = number of smoke dose units). According to this equation, the best logistic regression estimation of LD_{50} at 24 hours was 14.7 units of smoke. Data were insufficient for statistical analysis at 72 hours.

Carboxyhemoglobin levels immediately after smoke exposure are shown in Figure 6. Even 3 units of smoke raised the carboxyhemoglobin level over 40%. Eighteen units of smoke elevated the mean blood carboxyhemoglobin level to 85.4 ± 2.6%.

The arterial oxygen tension (PaO_2) of each group is shown in Figure 7. Control sheep had an average PaO_2 of 88.9 ± 1.2 torr (N = 12, electrode at 37 C). Sheep exposed to 9 units or more had significantly lower PaO_2 than the controls at both 24 and 72 hours after smoke exposure. At 24 hours after smoke inhalation, PaO_2 (y = torr) was negatively related to the number of units of smoke exposure (x = units): $y = 90.0 - 3.24x$ ($r^2 = 0.646$, N = 44, $p < 0.01$). The data were insufficient for statistical analysis at 72 hours.

At 24 hours, none of the sheep exposed to 9 units or less of smoke showed significant depression of plasma

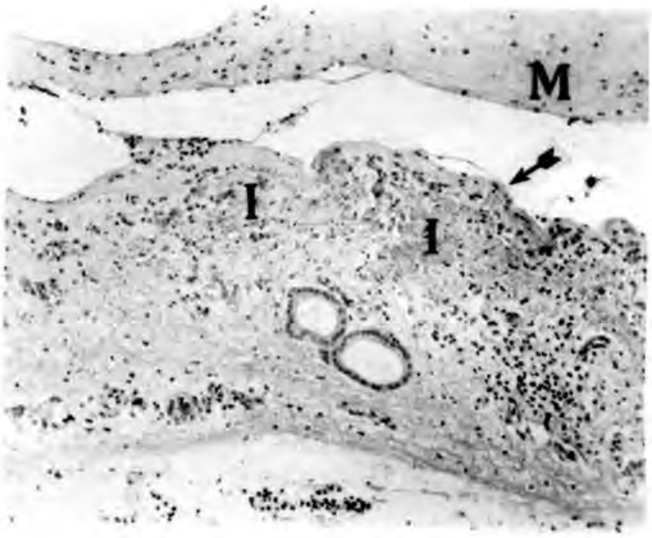

FIG. 4A. Histologic changes at 24 hours after exposure to 9 units of smoke. Note the sloughing of necrotic tracheal epithelium (arrow), the inflammatory cell infiltration (I), and the presence of a thick pseudomembrane (M). (Hematoxylin and eosin, original magnification ×370.)

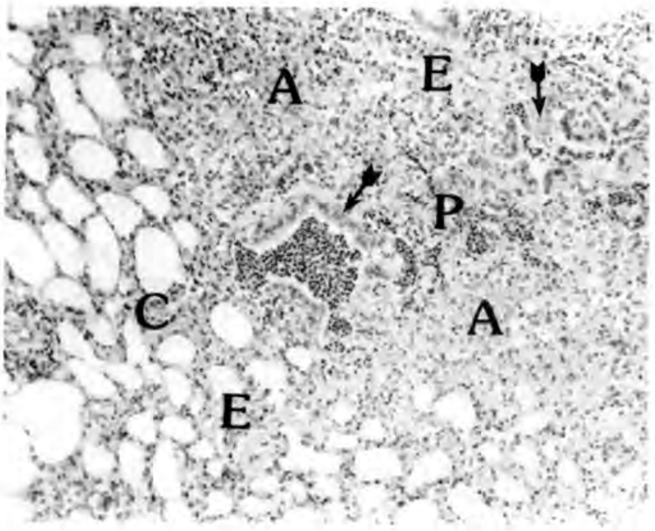

FIG. 4B. Parenchymal changes are shown. Occlusion of bronchioles (arrows) by inflammatory cells and necrotic debris is noted with concomitant atelectasis (A), congestion (C), edema (E), and pneumonia (P). (Hematoxylin and eosin, original magnification ×370.)

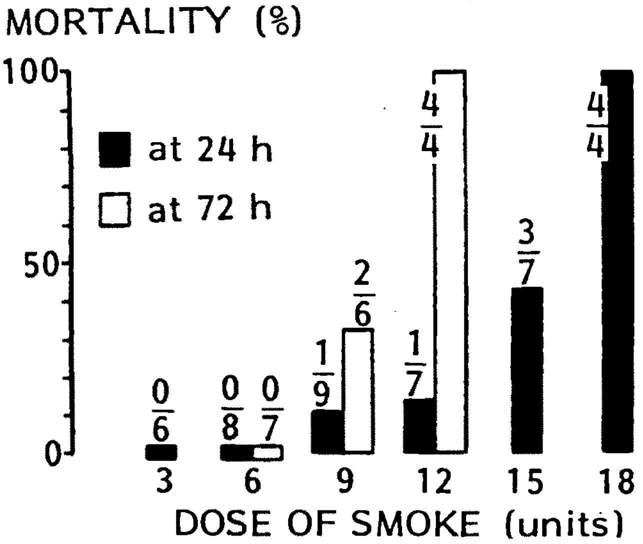

FIG. 5. Mortality at 24 hours (solid bars) and 72 hours (open bars) after smoke exposure. Mortality is shown as percentage. Fractions on the bars are actual number of dead sheep (numerator)/number of sheep studied (denominator). Mortality at 72 hours for 15 or 18 units of smoke exposure was not studied because 12 units of smoke was already fatal by 72 hours.

pH (Table 1). Some of the sheep exposed to 9 units or more had elevated plasma $PaCO_2$ at 24 hours, but this was not a consistent finding (Table 1). At 72 hours, surviving sheep exhibited no acidosis, but one had hypercapnea ($PaCO_2 = 42$ torr).

Mean blood pressure (mBP, y = torr) also showed dose responsiveness (Fig. 8) between 3 and 15 units of smoke (x = smoke units) at 24 hours: $y = 136.0 - 3.55x$ ($r^2 = 0.439$, $N = 32$, $p < 0.01$). Sheep exposed to 3 units of smoke showed highly elevated blood pressure and those exposed to 12 units or more had significantly lower blood pressure than others. The data at 72 hours were not sufficient for such analysis. Sheep exposed to 12 units or more also showed significantly increased PAP at 24 hours (Table 1).

Cardiac index (CI) was higher in the 3-unit and 6-unit groups than in controls at 24 hours, but the difference was not statistically significant (Table 1). At 9- and 12-unit doses, CI decreased progressively, but the CI of the 15-unit group did not differ significantly from control. A significant difference of CI was seen only between the 6-unit and 12-unit dose groups at 24 hours. At 24 hours, the left ventricular stroke work index (LVSWI) of the 12-unit group was significantly lower than the preinjury level. No significant differences in total peripheral resistance index (TPRI) were noted in any group.

Pulmonary resistance (PR) was significantly elevated at 24 hours in sheep exposed to 9 units or more and at 72 hours in sheep exposed to 9 units of smoke (Fig. 9). Lung static compliance changes were the reciprocal of

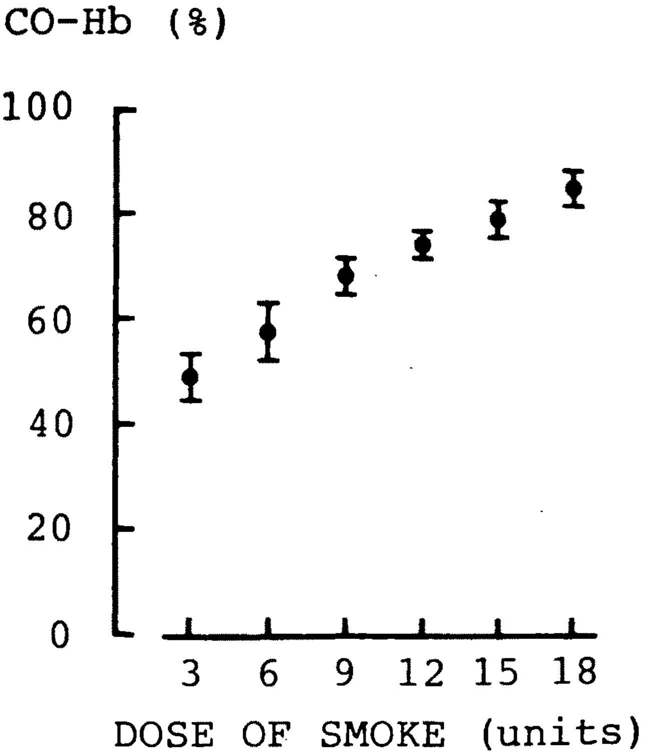

FIG. 6. Peak levels of carboxyhemoglobin (CO-Hb). Blood samples were taken immediately after smoke exposure from the external jugular vein.

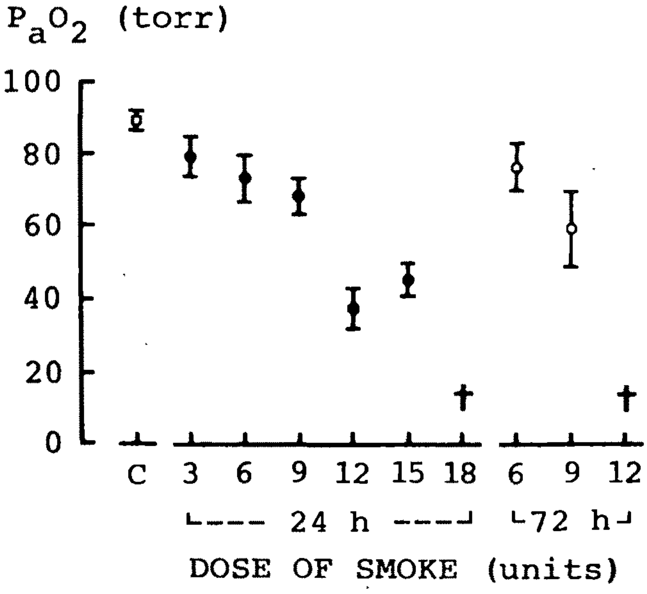

FIG. 7. Arterial oxygen tension (PaO_2) of the control (C) and smoke-exposed groups. Crosses (+) show that all the sheep in that group had died by the time of physiologic measurement. At 24 hours after smoke inhalation, PaO_2 (y = torr) was negatively related to the number of units of smoke expsoure (x = units): $y = 90.0 - 3.24x$ ($r^2 = 0.646$, $N = 44$, $p < 0.01$). The data at 72 hours were not sufficient for statistical analysis. Note that the values shown here are direct readings from the electrode set at 37 C. The actual PaO_2 in the sheep is 7–12 torr higher after temperature correction for their body temperature (39.5–40.0 C).

* $PaCO_2$ values are direct readings from the electrode set at 37 C.

mPAP = mean pulmonary artery pressure; LVSWI = left ventricular stroke work index (g-m/m^2); CI = cardiac index; TPRI = total peripheral resistance index (dynes sec m^2/cm^5); EVLWV = extravascular lung water volume.

those in PR; compliance was significantly lower at 24 hours in sheep exposed to 12 units or more and at 72 hours in sheep exposed to 9 units (Fig. 10).

At 24 hours, extravascular lung water was significantly elevated in sheep exposed to 12 units compared with the controls or to those sheep exposed to 9 units of smoke or less. No significant difference was found between the 12-unit and 15-unit groups (Table 1).

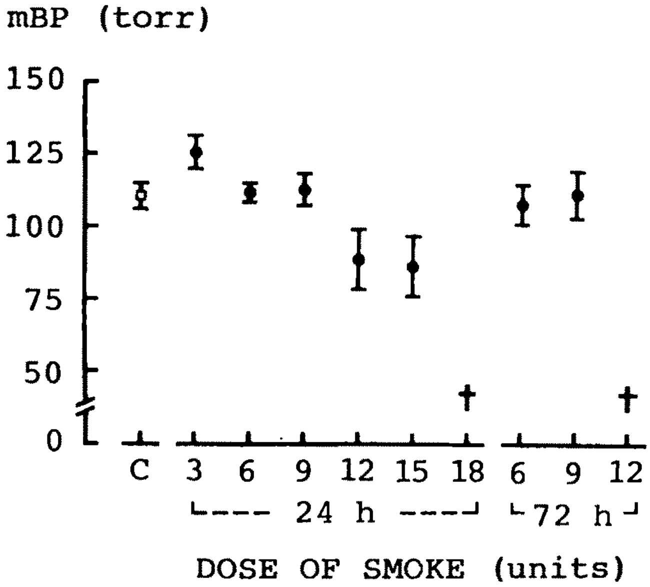

FIG. 8. Mean blood pressure (mBP) of each group. At 24 hours, mBP (y = torr) showed similar relationship to PaO_2 between 3 and 15 units of smoke (x = units): $y = 136.0 - 3.55x$ ($r^2 = 0.439$, N = 32, $p < 0.01$). The data at 72 hours were not sufficient for such analysis.

Discussion

In this model, anesthetized sheep were insufflated with smoke, using endotracheal intubation, to inflict a consistent reproducible injury to the lung. After smoke exposure, the sheep were extubated and allowed to breathe spontaneously. Twenty-four or 72 hours after smoke inhalation, the sheep were reanesthetized, intubated, and catheterized for physiologic evaluation. After a 2-hour stabilization period, cardiopulmonary indices were measured under general anesthesia and mechanical ventilation. We used alpha-chloralose as the anesthetic agent because this agent exerts only minimal effects on cardiopulmonary function.[18] We returned the sheep to the prone position as soon as the catheters were placed to avoid any adverse effects of the supine position. Prolonged supine positioning causes congestion in the lung, frothing, and cyanosis.[19] Sigh ventilation was used to prevent atelectasis, which is likely to develop in sheep, even in the prone position. In exposing the sheep to smoke, a tidal volume of 30 mL/kg was used. This tidal volume did not present a problem for the 24–40-kg sheep used in this study, but such a volume-to-weight ratio might produce hyperinflation of the alveoli in larger sheep.

To understand the significance and limits of the results of this study, several physiologic characteristics of sheep need be pointed out. In sheep, a major difference from humans is seen in the erythrocytes. Sheep not only have low Na-K pump activity, but also have relatively lower blood hemoglobin concentrations, higher P-50 values, lower 2,3-DPG levels, and a higher body temperature.[20–21] These differences must be taken into account when analyzing and comparing hemodynamics and oxygen transport in sheep and humans.[22] For example, actual PaO_2 at the sheep's body temperature (39.5–40 C) is usually 7–12 torr higher than the values obtained from blood gas analyzers with the electrode set at 37 C. Sheep also have very low plasma cholinesterase activity.[23] Interestingly, succinylcholine chloride did not have a prolonged effect in the study sheep.

Stephenson et al.[12] have suggested that the severity of smoke inhalation injury is dose-related, but physiologic measurements of dose responsiveness have not been made except for a mortality study in rats.[6] The sheep model of smoke inhalation injury used in these studies is reproducible and manifests dose responsiveness of hemodynamic and pulmonary variables that are most distinct at 24 hours. The lesser number of sheep studied at 72 hours and the narrower range of smoke doses used in the sheep studied at 72 hours may account for the poorer correlations noted at that time.

Mortality at 24 hours was well approximated by the logistic model (mortality = exp(y)/(1 + exp(y)), where $y = 0.535x - 7.865$ and x = number of smoke dose by units). This logistic model predicts mortality of 0.19% and 0.94% for 3 and 6 units of smoke exposure, respectively. Although all sheep given those doses of smoke were sacrificed after physiologic measurements at 24 or 72 hours, the clinical condition of all sheep was consistent with recovery from the inhalation injury and survival. In the sheep exposed to 6 units of smoke, none of the physiologic variables measured at 72 hours showed further deterioration from values measured at 24 hours after smoke exposure. Histologically, tracheal epithelium examined 72 hours after 6 units of smoke exposure showed metaplasia, suggesting early healing. These physiologic and histologic findings suggest that damage from 6 units of smoke is reversible. On the other hand, a 9-unit or greater dose of smoke caused progressive changes resulting in much higher mortality and further deterioration in lung function by 72 hours after exposure. Histologic changes in those sheep were also progressive; the airway epithelium showed further deterioration and congestion and atelectasis of the lung were more severe at 72 hours. The parenchymal changes were most distinct in dependent areas of the lung. This accumulation of occlusive exudate in dependent airways is probably related both to the effect of gravity and to the loss of effective normal elimination of exudate by ciliary action and coughing.

The dose-response patterns of selected physiologic indices were analyzed using the data at 24 hours after smoke exposure. Four patterns were observed (Fig. 11): (1) No apparent smoke dose effect, as exemplified by TPRI. (2) An apparent threshold effect, *i.e.*, poor linear correlation with dose ($r^2 < 0.20$), but significant change at 12-unit and/or 15-unit doses and no significant difference between those two groups: pH, peripheral vascular resistance index (PVRI), and right ventricular stroke work index (RVSWI). (3) A linear relationship (0.20

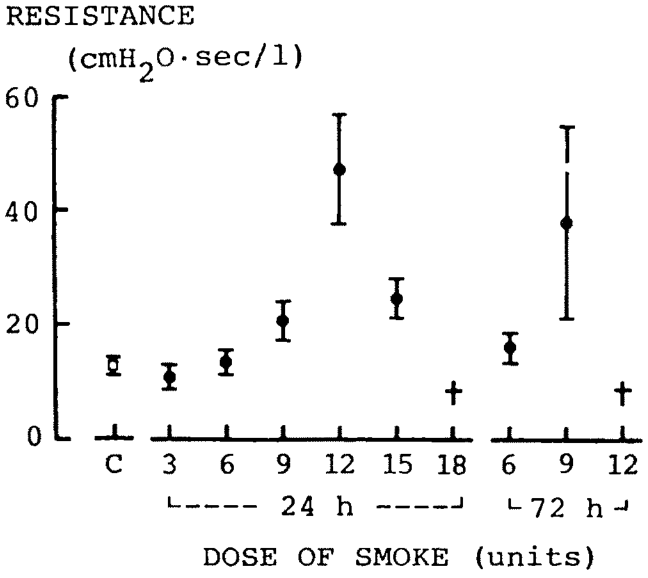

FIG. 9. Pulmonary resistance (PR) of each group. PR was calculated by the following equation: PR = (mouth pressure − intrapleural pressure)/flow rate. Mouth pressure means pressure at the connection of respiratory circuit and tracheal tube. PR includes airway resistance plus pulmonary tissue resistance.[28]

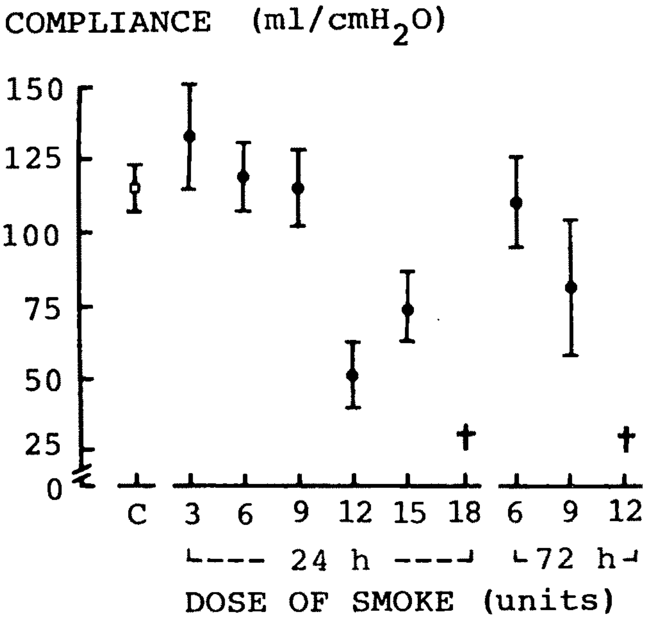

FIG. 10. Static compliance of each group. Static compliance was calculated from the following equation at end-inflation: Compliance = volume change/transpulmonary pressure. Change in compliance was a mirror image of that of pulmonary resistance.

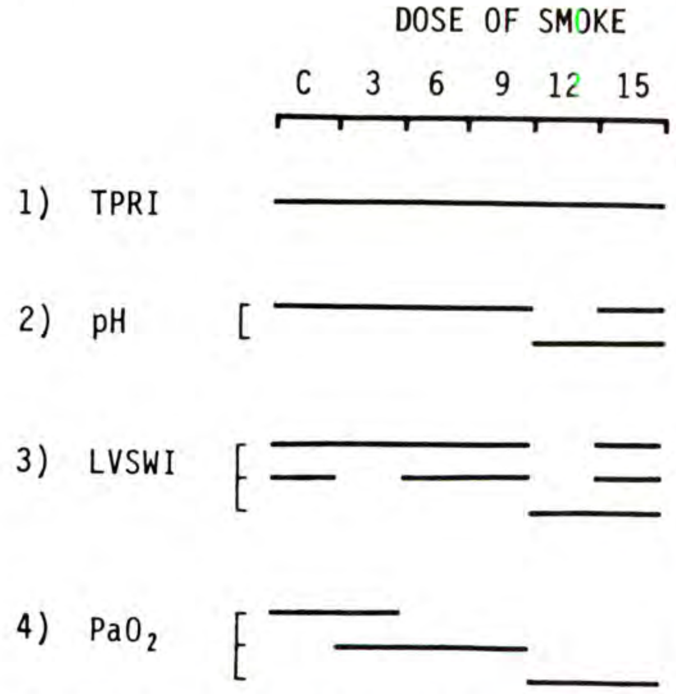

FIG. 11. Four patterns of response in physiologic indices at 24 hours after smoke exposure. Multiple comparisons by the Student-Newman-Keuls multiple range method are described by the underlining method. Groups underlined by the same line are not distinguishable from one another. Typical examples of the four patterns are shown. (1) No apparent smoke dose effect. (2) An apparent threshold effect. (3) A linear relationship ($0.20 < r^2 < 0.40$) over at least a portion of the smoke dosage range. (4) A good linear relationship ($r^2 > 0.40$) over the entire range of doses of smoke. See text for details.

$< r^2 < 0.40$) over at least a portion of the smoke dosage range: $PaCO_2$, PR, static compliance, lung water, LVSWI, and CI, where LVSWI = between 3 and 15 units and CI = between 6 and 15 units. (4) A good linear relationship ($r^2 > 0.40$) over the entire range of doses of smoke: PaO_2 ($r^2 = 0.646$), mBP ($r^2 = 0.439$), and mPAP ($r^2 = 0.407$), where mBP = between 3 and 15 units.

TPRI was maintained within the normal range in all surviving sheep, suggesting that the TPRI is well protected by homeostatic mechanisms and is not an index of the severity of inhalation injury. Indices showing threshold changes (pH, PVRI, and RVSWI) also appear to be well maintained until a severe insult is incurred. Changes in these indices are indicative of a significant smoke inhalation injury. Once a threshold level was exceeded, no significant further change in these physiologic indices was noted in the 15-unit group compared with the 12-unit group. Indices that manifested the third or fourth patterns showed moderate to good correlation between the number of units of smoke and magnitude of change.

For some variables, a significant difference from the control level was not seen (CI) nor was observed only after exposure to 12 units of smoke ($PaCO_2$, LVSWI, PR, static compliance, lung water, mBP, and PAP) when assessed by analysis of variance. PaO_2 showed the highest correlation coefficient ($r^2 = 0.646$), but a significant difference from the control level was observed only in groups exposed to 9 units of smoke or more. The dose-response curve of PaO_2 (Fig. 7) and the fact that changes of most of the cardiopulmonary indices became significant only after 12-unit exposure suggest that the dose-response curve is sigmoid in shape rather than linear, and that the steep portion of the curve is located between 9 and 12 smoke units (Fig. 12). The steep portion of the curve might also be approximated by curved linear (polynomial) functions, reflecting the progressive nature of such injury. Stephenson et al. pointed out that, by inference from the literature, there is no variable to reliably predict lung injury due to smoke inhalation.[12] That failure may be related to the sigmoid nature of the dose-response curve suggested by this study. To describe the sigmoid curve precisely, it will be necessary to assess the physiologic response over a wide range of inhalation injury severity. Several of the indices examined in this

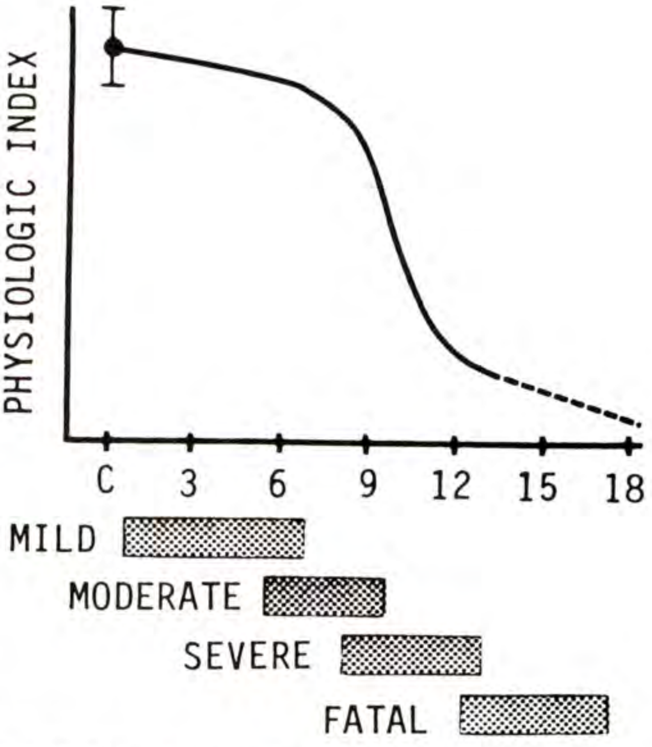

FIG. 12. Schematic presentation of dose-response curve of sigmoid nature and grading of smoke inhalation injury. Ordinate represents physiologic indices and abscissa shows doses of smoke in units. Statistical significance is not detectable at doses below 9 units. Substantial change occurs between 9 and 12 units. The plateau on the right side (shown as an interrupted line) is not clearly observed because those higher doses are fatal. The bars indicate the grading of smoke inhalation injury. See text for details.

study do not appear to be sensitive indicators of injury severity since they were not significantly altered by nonlethal doses of smoke.

Although others have reported no significant changes in PAP after smoke inhalation and have attributed pulmonary edema in such models to increased capillary permeability,[11] we observed a significant increase in PAP in sheep exposed to high doses (12 and 15 units) of smoke (Table 1). Judging from the mortality in the sheep studied by Herndon et al.[11] (13 of 27 at 72 hours), that severity of inhalation injury corresponded to little more than that caused by 9 units of smoke in our study. The change in PAP that we observed was modest until the smoke dose exceeded 9 units, above which it increased greatly. The parallelism of changes in PAP and extravascular lung water volume in the current study suggests that elevation of intravascular pressure may contribute to pulmonary edema after smoke inhalation injury.

The effect of inhalation injury on extravascular lung water volume is unclear. Markedly different thermal-dye measurements of extravascular lung water volume have been reported.[24,25] As an explanation of the discrepancies, Prien et al. have recently reported that pulmonary edema of smoke inhalation was undetectable by indicator-dilution technique in a sheep model.[26] That finding may reflect differences between patients with burns and inhalation injury and experimental models with smoke inhalation alone. In laboratory studies, including our study, the animals did not have cutaneous burns and they did not receive large volumes of resuscitation fluid. Since the composition of administered fluids affects lung water accumulation in burn patients,[27] differences in resuscitation regimens may account for some of the reported differences in lung water measured in burn patients. We showed in this study that lung water change was not significant until the severity of inhalation injury reached a certain level, *i.e.,* 12 units of smoke, which caused 100% mortality within 72 hours. This indicates that, apart from any insensitivity of the indicator-dilution methods, extravascular lung water volume may not be increased in less severe inhalation injury.

It is important to identify the severity as well as the presence of inhalation injury. In this study, PaO_2 showed the best dose-response relationship, and although it appears to be the most reliable index for estimating the severity of smoke inhalation injury, PaO_2 changes are not specific to such injury. It may be more useful to grade smoke inhalation as mild (3–6 units), moderate (6–9 units), severe (9–12 units), and invariably fatal (over 12 units) (Fig. 12). Mild smoke inhalation injury did not cause death by itself and all the physiologic indices remained normal. In some animals with mild injury, no tracheal pseudomembrane formation was evident and when present was minimal. Diagnosis of smoke inhalation injury of this degree would be difficult without histologic examination at an appropriate time. Moderate injury was associated with a mortality of 30% by 72 hours. Pseudomembrane formation in the major airways was always evident but many physiologic indices still did not change significantly. Severe inhalation injury caused 10–14% mortality by 24 hours and 30–100% mortality by 72 hours. A thick pseudomembrane formed in the airways and physiologic indices showed significant changes. The variability of changes noted in the various indices may be attributable to the sigmoid shape of the dose-response curve. Invariably, fatal injury caused total loss of airway epithelium and 100% mortality. Although this grading is based on an experimental model of smoke inhalation without cutaneous burns, a similar grading for smoke inhalation in burn patients may be useful in evaluating the severity of smoke inhalation and assessing treatment outcome. This dose-responsive sheep model can now be used to determine the pathogenesis of inhalation injury, to assess the effect of associated burn injury, and to evaluate the effectiveness of therapeutic interventions.

Diagnosis of Varicocele and Postoperative Evaluation Using Inguinal Ultrasonography

RUBEN ORDA, M.D., M.S.,* JOEL SAYFAN, M.D.,* HANNA MANOR, M.D.,† ELA WITZ, M.D.,† and YIGAL SOFER, M.D.‡

Ultrasonographic real-time imaging and measurements of spermatic veins in the inguinal canal were evaluated in two groups of patients: 20 young men with varicocele and 18 controls. Examinations were performed with the patient in an upright relaxed position, and performing the Valsalva maneuver. The increase in diameter of the main vein during Valsalva maneuver was considered to quantitatively represent venous reflux. The data obtained were correlated with pre- and postoperative clinical findings. This method of evaluation proved to be a useful noninvasive diagnostic modality for detecting varicocele and for assessing treatment results. On the basis of venous diameters and reflux values, a classification of varicocele is proposed. Such an objective method of grading would eliminate the subjective impression and interpretation factors of the examiner.

DIAGNOSIS OF VARICOCELE is important since it has been found in as many as 21–39% of men attending infertility clinics.[1] Small varicoceles may have the same impact on fertility as large lesions.[2] Recognition of the dilated veins is usually made by physical examination. The lack of accuracy of diagnosis based only on visualization and palpation is obvious and many small lesions may escape detection.

Varicoceles are commonly classified as small, moderate, or large, according to a subjective grading of venous size and reflux.[2] Retrograde venography is an objective and precise diagnostic method, but it is invasive and cannot be used for screening. More recently, several noninvasive methods have been proposed for improving the diagnosis of varicocele, mainly for small lesions in which recognition of venous dilation and reflux is problematic. A recent multicenter trial organized by the World Health Organization (WHO) reported satisfactory results using a combination of Doppler sonography and contact scrotal termography.[3]

From the Department of Surgery A, the Institute of Diagnostic Radiology,† and the Department of Obstetrics and Gynecology,‡ Assaf Harofeh Medical Center, Sackler Faculty of Medicine, Tel Aviv University, Zerifin, Israel*

The use of ultrasonography for scrotal vein imaging has been scarcely reported in the radiologic literature[4-6] and did not have impact on current clinical evaluation of varicocele. Sonography was not even mentioned in the WHO's multicenter study as an actual diagnostic modality.

The current prospective controlled study was done to assess the value of real-time ultrasonography of spermatic veins at the inguinal canal level, for diagnosis of varicocele and for postoperative evaluation.

Materials and Methods

The left spermatic cord veins were detected by inguinal imaging ultrasonography in two groups of patients: (1) varicocele group: comprising 20 young men with clinically diagnosed left varicocele (age range: 16–23 years, mean age: 19 years), and (2) control group: comprising 18 young men referred to surgery because of minor disorders unrelated to the genital area. Absence of genital abnormalities and, specifically, varicocele was confirmed by physical examination. Age range was 16–38 years, mean age was 25 years.

Imaging of the Left Spermatic Cord Veins

The examinations were performed using a B-mode gray-scale ultrasound with 5-MHz transducer (Picker International Inc., GmbH, München, West Germany) and a Dynex Elscint with 5-MHz and high-resolution 10-MHz transducer (Elscint Ltd., Haifa, Israel).

In both groups the patients were examined in an upright position. Imaging of the venous plexus was obtained by direct contact with the skin in the inguinal

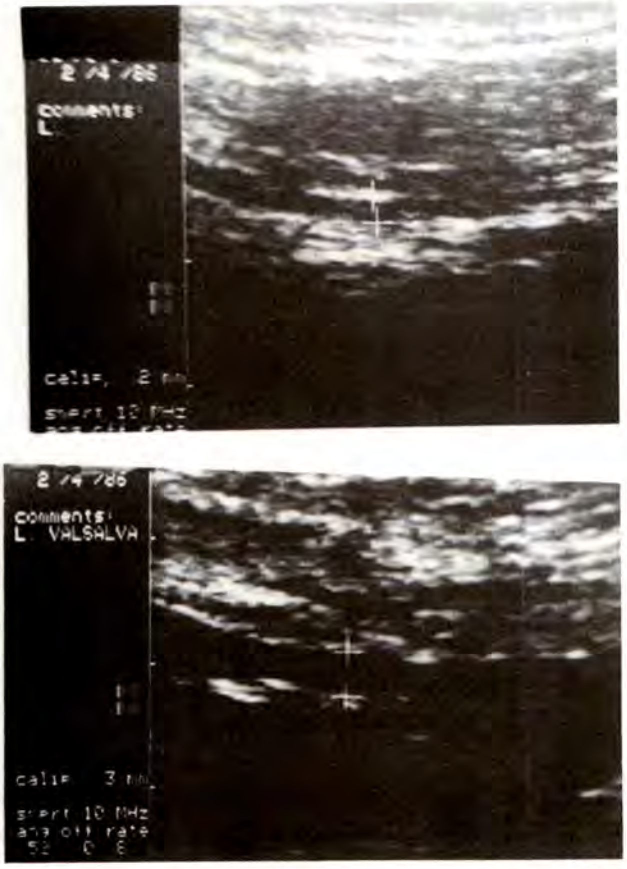

FIG. 1. Longitudinal sonogram of left spermatic cord at the inguinal canal level (10-MH transducer). Top: relaxed standing position; diameter of the dominant vein: 2 mm. Bottom: during Valsalva maneuver, the dominant vein dilated to 3 mm. Diagnosis: small varicocele, reflux of 1 mm.

region. The transducer was positioned for longitudinal axis scanning of the spermatic cord in the inguinal canal, parallel to the medial half of the inguinal ligament. Scanning was performed with 45° inclination of the transducer. The diameter of the dominant draining vein was measured with the patient relaxed and while performing the Valsalva maneuver. Measurements in the varicocele group were performed before operation and 3 months after operation. The patients were operated on by the classic retroperitoneal high ligation technique.

TABLE 1. *Mean Diameters of Dominant Veins and Venous Reflux in the Left Spermatic Cord*

	Varicocele Group		
	Before Operation	After Operation	Control Group
Diameter during relaxation (mm)	4.5	2.0	2.2
Diameter during Valsalva maneuver (mm)	5.7	2.8	2.7
Reflux (increase in diameter during Valsalva) (mm)	1.2 ($p < 0.001$)*	0.8 (NS)	0.5 (NS)

* Statistical analysis by Student's t-test.

We calculated the difference between the main diameter of the dominant draining vein during Valsalva maneuver, and in relaxed upright position. This value was considered as the numeric expression of venous reflux into the pampiniform plexus. The ultrasonographic measurements of the varicocele and control groups were compared.

Results

Longitudinal sonograms of the left spermatic cord permitted good visualization of the venous channels. Particularly clear imaging, even in small lesions, was obtained by using the high-resolution 10-MHz transducer. When the spermatic cord was scanned at the level of the inguinal canal, a dominant draining vein could be identified and its diameter measured. The main vein was accompanied by smaller channels running longitudinally, the complex constituting the pampiniform plexus (Fig. 1).

Varicocele Group

Preoperative values. The mean diameter of the dominant veins in the left spermatic cord during normal respiration in erect position was 4.5 mm. The mean diameter increased to 5.7 mm during Valsalva maneuver. The difference (numeric expression of venous reflux) of 1.2 mm was significant ($p < 0.001$) by the Student's t-test.

Postoperative values. During relaxation the mean venous diameter was 2 mm, and during the Valsalva maneuver was 2.8 mm. The difference of 0.8 mm was not significant.

Control Group

The mean diameter of the main veins during relaxation was 2.2 mm. When the patients performed the Valsalva maneuver, the mean diameter increased to 2.7 mm. The numeric expression of venous reflux of 0.5 mm was not significant.

Table 1 summarizes the measurements of mean diameters of the dominant veins and of venous reflux in the left spermatic cord in both groups.

The varicocele group was further divided into three subgroups according to the size of the main left spermatic veins (Table 2): (1) Small varicocele: mean diameter of main veins in relaxed standing position ranged between 2.5 and 4.0 mm. During Valsalva maneuver there was an increase of about 1.0 mm. (2) Moderate varicocele: mean diameter of main veins oscillated between 4.0 and 5.0 mm and during the Valsalva maneuver increased 1.2–1.5 mm. (3) Large varicocele: mean dominant vein diameter during normal respiration was greater than 5.0 mm, and during the Valsalva maneuver there was an increase of more than 1.5 mm.

Discussion

Our results indicate that varicocele can be accurately diagnosed by ultrasonograhic imaging. High-resolution transducers can reveal even small varicoceles. Current methods of diagnosis, namely physical examination, termography, or Doppler stethoscope, are largely dependent on the subjective impression and interpretation of the examiner, yielding imprecise and noncomparable data. This situation does not permit conduction of truly reproducible studies, and no uniform classification can be used.

Previous reports showed the ability of ultrasonography for imaging and even measuring the diameter of normal and dilated scrotal veins.[4–6] We performed the measurements of the spermatic cord veins at the inguinal level. The fact that the average diameter of any venous network increases centripetally explains why the values of our control group were slightly higher than the 2 mm described as the upper normal limit in previous reports. We consider the spermatic cord veins in the inguinal canal as the appropriate evaluation site because of their longitudinal alignment in contrast to the convoluted and irregular venous arrangement at the scrotal level.

In the varicocele group the mean diameter was 4.5 mm in relaxation and 5.7 mm during the Valsalva maneuver. These values are again consistent with previous publications, which found scrotal veins of 5–6 mm diameter in varicocele patients. It seems that these values of normal and pathologic calibers of veins can be accepted as guidelines to sonographic diagnosis of varicocele (Table 1). The difference between the mean diameters of the dominant draining vein during Valsalva maneuver and in relaxed standing position ranged between 1.0 and 1.7 mm. These values were objective representatives of the venous reflux into the pampiniform plexus. When we consider the measurements performed in the varicocele group before and after operation, it is striking that the postoperative values became similar to those obtained in the control group. The pre-operative reflux was highly significant and became nonsignificant after surgical treatment (Table 1). These data suggest that ultrasonography can be useful in the follow-up of treatment results, giving objective definition of success or failure.

TABLE 2. *Suggested Classification of Varicocele*

	Normal Values	Small	Moderate	Large
Dominant vein diameter (standing relaxed) (mm)	0.5–2.5	2.5–4.0	4.0–5.0	>5.0
Reflux (mm)	0.5–1.0	1.0–1.2	1.2–1.5	>1.5

The ability to provide measurements data is one of the main advantages of this noninvasive method. Measurements of spermatic vein diameter and of venous reflux enabled us to classify varicoceles as small, moderate, and large (Table 2). This "quantitative" ultrasonographic classification is more precise and comparable than previous classifications based on physical examination only.

In conclusion, ultrasonographic imaging and measuring of the spermatic cord veins at the inguinal canal level can be recommended as an accurate screening procedure for: (1) diagnosis of varicocele, (2) clinical classification, and (3) assessment of treatment results. However, further studies are necessary to determine the sensibility of this method for detecting very small or subtle varicoceles.

Origin of the Right Pulmonary Artery from the Ascending Aorta

GREGORY P. FONTANA, M.D., MADISON S. SPACH, M.D., ERIC L. EFFMANN, M.D., and DAVID C. SABISTON, JR., M.D.

Origin of the right pulmonary artery from the aorta is a congenital malformation usually associated with serious symptoms in the first year of life and characterized by a poor prognosis. Sixty-five patients with this disorder have been reviewed in the literature, and 95% presented during the first year with signs of congestive heart failure. All had cardiomegaly by radiographic and electrocardiographic examination. An accurate diagnosis was established by cineangiography, and associated cardiovascular anomalies were present in 85%. Origin of the *right* pulmonary artery from the ascending aorta is much more common than origin of the left pulmonary artery from this vessel (8 to 1). Twenty-three patients were managed without operation with a 30% 1-year survival rate. Among those patients managed surgically, the survival rate was 84% at 1 year. It is now clear that operation should be done as early as possible to prevent irreversible changes occurring in the pulmonary arterial vasculature since microscopic features of pulmonary hypertension have been seen during the first month of life. One patient was operated on at 5 months with correction of the deformity. The pulmonary arterial pressure decreased to normal after operation. This child is now asymptomatic and his 10-year postoperative follow-up is the longest found in the literature.

From the Departments of Surgery, Pediatrics, and Radiology, Duke University Medical Center, Durham, North Carolina

ORIGIN OF A PULMONARY ARTERY from the ascending aorta is a rare congenital malformation of the great vessels that is usually fatal without early surgical correction. The first patient, a 25-year-old woman, was reported by Fraentzel in 1868 and died of congestive heart failure.[1] Postmortem examination revealed an aortopulmonary window and origin of the right pulmonary artery from the ascending aorta. It has been emphasized that there are at least three different cardiovascular malformations that have been given the same terminology, including: (1) origin of the right pulmonary artery (RPA) or left pulmonary artery (LPA) from the ascending aorta, (2) absence of the proximal portion of the RPA or LPA with distal RPA or LPA supplied *via* a patient ductus arteriosus (PDA), and (3) absence of a proximal pulmonary artery branch with the distal RPA or LPA supplied by an aortopulmonary collateral other than a PDA.[2] The latter two conditions differ from the first in embryologic development and physiologic behavior. When the RPA or LPA originate from a PDA or collateral arteries, the pressure in the vessel is often elevated but less than systemic pressure, whereas in aortic origin of the pulmonary artery, the pressure is at the systemic level.

Physiologically, the alteration creates a large left-to-right shunt from the aorta to the pulmonary circulation and then to the left atrium. The contralateral lung is therefore subjected to the entire right ventricular output in addition to flow contributed by associated anomalies, *e.g.*, PDA, atrial septal defect (ASD), ventricular septal defect (VSD), or aortopulmonary septal defect, which have been present in greater than 60% of previous reports. The pulmonary artery pressures on the contralateral side are elevated.

Clinical Presentation

Two patients with origin of the RPA from the ascending aorta have been seen in this medical center. The first patient died in the first month of life of congestive heart failure. The postmortem findings included origin of the RPA from the ascending aorta as well as a small PDA.[3] The second patient was a 7-pound male infant and product of an uncomplicated pregnancy, labor, and delivery to a 20-year-old primapara. Examination was described as normal at birth and the infant was discharged on the second day of life. During his first month, the child tired

Submitted for publication: January 15, 1987.

easily with feeding and occasionally became short of breath with activity. At 1 month of age a holosystolic murmur was heard, and the child was referred to the Duke University Medical Center for further evaluation.

On physical examination, he was a normal-appearing noncyanotic white male infant with a regular pulse of 180 beats per minute, respiratory rate of 44 per minute, and blood pressure of 110/52 mmHg. The lungs were clear, the precordium was active, and a thrill was noted along the left midclavicular line. Auscultation revealed a normal S1, widely split S2, and a III–IV/VI holosystolic murmur along the left sternal border and at the apex. There were no diastolic murmurs. The remainder of the physical examination was normal.

Chest films were significant for mild cardiomegaly and bilateral prominence of the pulmonary vasculature, right greater than left (Fig. 1). The electrocardiogram showed bilateral ventricular hypertrophy. At 2.5 months of age, cardiac catheterization, including biplane cineangiography, was performed. The significant findings included aortic origin of the RPA and a patent foramen ovale without a significant shunt. The ductus arteriosus was described as not patent. LPA pressure was two-thirds systemic, and the ventricular septum was intact. Pressure and oxygen saturation data are shown in Table 1. After catheterization, the patient was treated medically with digoxin, and over a 6-week period symptomatic improvement was evident. Failure to thrive at approximately 5 months of age led to performance of a corrective surgical procedure.

The operation was performed through a median sternotomy (Figs. 2A–C). The pericardium was opened and with leftward retraction of the aorta, the RPA was seen to arise from the posterior aspect of the ascending aorta. At its origin, the RPA measured 12 mm in diameter. A 4-mm ductus arteriosus was noted to be patent and was closed. A partial occlusion clamp was placed on the posterior portion of the ascending aorta at the origin of the RPA. Another arterial clamp was placed distally on the RPA. The RPA was divided at its origin and the aortic defect was oversewn. A 12-mm woven Dacron graft was preclotted and anastomosed to the distal RPA. A partial occlusion clamp was placed on the right lateral aspect of the main pulmonary artery (MPA) just distal to the pulmonary valve. The graft was then anastomosed to the MPA with a continuous suture of 5-0 Ticron. Immediately after opening the graft, the systolic pressure in the RPA was 20 mmHg and was 22 mmHg in the LPA. On the ninth postoperative day, a ventilation/perfusion scan revealed bilateral pulmonary flow *via* the MPA. Digoxin therapy was continued for approximately 3 months and then discontinued.

One year after operation the patient was asymptomatic and had resumed normal growth. Follow-up catheterization performed in February 1977, showed mild proximal stenosis of the RPA, a patent foramen ovale without significant interatrial shunt, and pressure and oxygen saturation data as shown in Table 1. The electrocardiogram (EKG) at that time showed mild right ventricular hypertrophy, and a ventilation/perfusion scan was considered normal.

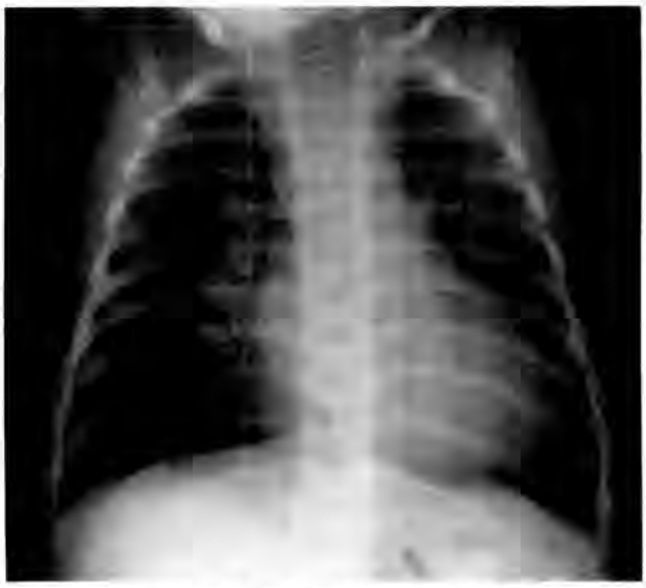

FIG. 1. Preoperative chest film showing mild cardiomegaly and bilateral prominence of the pulmonary vasculature most prominent on the right side.

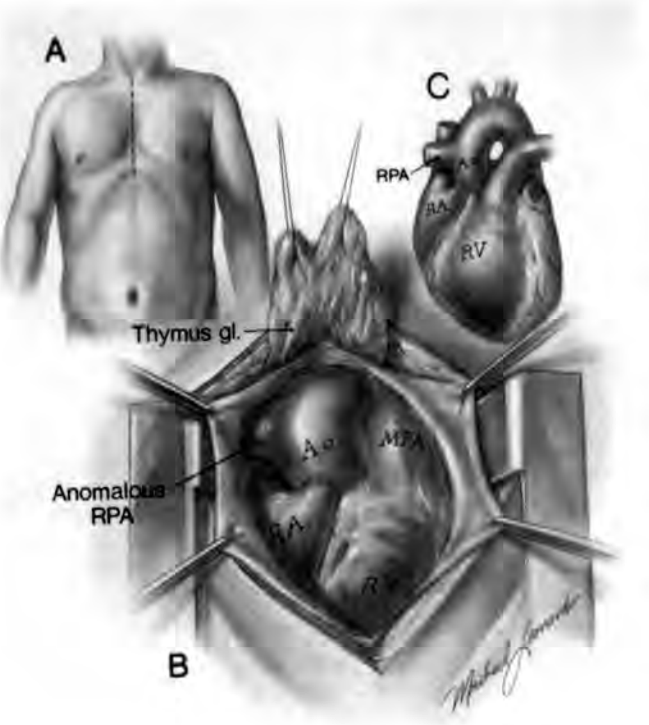

FIG. 2A. A: Median sternotomy. B: The pericardium is opened. C: The right pulmonary artery is seen as it arises from the ascending aorta.

Since 1977, the patient has maintained normal growth and development with no symptoms or signs of congestive heart failure. The EKG has become normal since operation and the chest films reveal a normal cardiothoracic ratio. The lung fields indicate a right-sided oligemia with compensatory left-sided hyperemia (Fig. 3). The patient had development of reactive airway disease at age 5, but has responded to medical therapy and has had no bronchospastic episodes for the past 2 years.

In 1983, a radionuclide angiogram was performed, revealing 39% of the right ventricular output distributed to the right lung, and 61% to the left lung. Radionuclide angiogram in 1986 showed delayed flow to the right lung and normal ventricular function. A ventilation/perfusion scan was performed, which revealed that 14% of the right ventricular output perfused the right lung, whereas 86% perfused the left side (Fig. 4). The ventilation scan was normal.

Review of the Literature

Sixty-five patients with true origin of the RPA from the ascending aorta have been reported in the English literature.[1-44] The distribution was males (64%) and females (36%). Almost all patients (95%) presented during infancy with signs of congestive heart failure, including respiratory distress, tachycardia, and failure to thrive. All those examined had cardiac murmurs, and 41% either presented with or had a history of cyanosis. One patient had hemoptysis.

In the 48 patients in whom chest films were reported, cardiomegaly was present as well as abnormalities in pulmonary vascularity. Bilateral increased flow was noted in 65% and increased flow on the right *versus* the left occurred in 35%. There were no instances of prominent pulmonary vascularity on the left side only. EKGs (48 patients) showed nonspecific findings of right ventricular hypertrophy (59%), left ventricular hypertrophy (6%), or biventricular hypertrophy (35%). Aortic origin of the RPA associated with PDA were in all three electrocardiographic categories. Arterial blood oxygen saturation was normal in those patients without a reason for substantial reduction in gas exchange, *i.e.*, pulmonary edema or bronchopneumonia. Two-dimensional echocardiography was performed in some patients and the short-axis viewing from the suprasternal notch position accurately demonstrated the anomaly in the aorta.

Preoperative or premortem diagnosis by cardiac catheterization was obtained in 73% of patients. Preopera-

tive misdiagnosis at catheterization occurred in three patients. In the first patient, a cineangiogram was not performed,[4] and the preoperative diagnosis was an isolated PDA. Ligation of the PDA was performed with subsequent deterioration of the patient, leading to death on the day of operation. A diagnosis of aortic origin of the RPA was made at autopsy. In the other two patients, abnormal origin of the RPA was *not* noted on cineangiogram before operation. After finding the anomaly during operation, the films were reviewed and the lesion was identified retrospectively.[44]

The most common anomaly associated with ascending aortic origin of the RPA was PDA (68%), followed by aortopulmonary septal defect (15%), hypoplastic or interrupted aortic arch (11%), patent foramen ovale (8%), ventricular septal defect (8%), atrial septal defect (8%), coarctation of the aorta (5%), tetralogy of Fallot (3%), and tricuspid atresia (2%). There were no associated anomalies found in 15% of patients (Table 2). A syndrome of aortopulmonary septal defect (APSD), hypoplastic or interrupted aortic arch, intact ventricular septum, PDA, and aortic origin of the RPA has been reported in nine patients.[41–44]

Systemic pressures in the RPA were found in all patients who had cardiac catheterization. LPA pressures were greater than or equal to two-thirds systemic pressure. Lung biopsy at operation or pathologic section at postmortem examination was obtained in 23 patients. Normal findings were present in five patients (age at examination: 3 days to 2 months). Intimal changes were present in eight patients (age at examination: 1 month to 21 years). Medial hypertrophy was seen in 16 patients (age at examination: 1 month to 21 years). In the major-

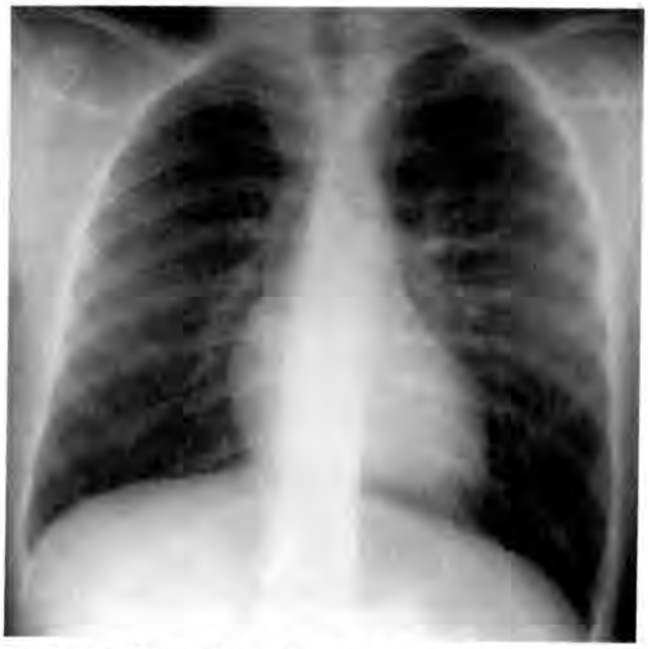

FIG. 3. Chest film at 10-year follow-up with normal-sized heart and diminution of right hilum and right pulmonary arteries. The left hilum and left pulmonary arteries are prominent.

ity of patients (67%) in whom pathologic changes were present, the findings were bilaterally symmetrical. The others had various degrees of medial and intimal abnormalities that occurred asymmetrically. It has been suggested that the differential development of pulmonary obstructive vascular disease is related to the disparate oxygen content of blood delivered to the affected side.[23] Nonparametric analysis of age *versus* onset of pathologic changes was significant to $p < 0.001$. Nonparametric analysis using the Kolmogorov-Smirnov Two-Sample Test was required for analysis of these data because of the effect two long-term survivors had on means and standard deviation, leading to failure of parametric analysis. Although both intimal and medial changes were observed in patients at 1 month of age, medial hypertrophy alone was seen in many patients 1–6 months of age and appeared to precede development of intimal hyperplasia. Due to the small sample size and wide range of ages, this did not achieve statistical significance.

Twenty-three patients were managed medically or had no treatment. The natural history without operation is illustrated in Figure 5. Thirty-five per cent died in the first month of life and 70% died by the age of 1 year. There were only four long-term survivors (17% living beyond 10 years) in the nonsurgical group. One patient with aortic origin of the RPA, tricuspid atresia, VSD, and hypoplasia of the right side of the heart, was surprisingly doing well with minimal exercise intolerance at the age of 9.[22] In this patient, anomalous origin of the RPA was the major source of pulmonary blood flow. The other long-term survivor was a 21-year-old woman, with an associated PDA, who was deemed inoperable at age 18 years secondary to "irreversible" pulmonary hypertension.[21] At that time, the patient had generalized cyanosis accompanied by exercise intolerance and episodes of hemoptysis. Right-to-left shunting was present at the level of the ductus arteriosus. She was attending college and her clinical status was stable at age 21 years. There were two long-term survivors with aortopulmonary septal defect, PDA, hypoplastic or interrupted aortic arch, and aortic origin of the RPA, both of whom died of profound congestive heart failure with postmortem evidence of severe pulmonary hypertension.[41,42]

Many procedures have been used to palliate or correct aortic origin of the RPA and its associated anomalies (Table 3). PDA ligation alone[4,10] and PDA ligation in association with RPA ligation[9,13] were uniformly unsuccessful and were performed early in the history of the treatment of this disorder. The first successful anatomic repair was reported by Armer et al. in 1961 with inter-

position of a Dacron graft between the RPA and the MPA (end-to-side).[5] A report by Caro et al. in 1957 of successful repair of anomalous origin of the RPA using an Ivalon interposition graft represented a patient in whom the anomalous RPA originated from the *innominate* artery.[45] The first successful primary repair was reported by Kirkpatrick et al. in 1967.[14] Both primary repair and graft interposition have been used since their respective first descriptions. Primary repair is generally reserved for those patients in whom the RPA originates from the posterior aspect of the aorta in close proximity to the MPA. When the RPA originates from the right lateral aspect of the aorta, the right hilum is often mobilized medially to allow apposition of the RPA and MPA without tension. Alternatively, interposition synthetic graft is placed either anterior or posterior to the aorta.

Three different types of primary repair have been performed, the most common (20 patients) being an anastomosis of the RPA to the MPA posterior to the aorta in an end-to-side fashion. One side-to-side repair was made in association with a VSD closure in a patient who had previous pulmonary artery banding.[18] In this patient, the aorta was clamped just proximal to the innominate artery after establishment of cardiopulmonary bypass. A vertical aortotomy was made and a right-angle clamp was passed through the orifice of the RPA. The left posterior aspect of the vessel was retracted to the left, placing it in apposition to the MPA. A side-to-side anastomosis was then performed. The origin of the RPA was closed through the aortotomy with interrupted sutures. A creative third method was performed in only one patient in whom the length of the RPA was inadequate for primary anastomosis.[29] Instead of using a graft, a modified primary repair was performed. After cardiopulmonary bypass was established and the aorta cross-clamped just proximal to the innominate artery, the anterior aspect of the aorta was incised transversly at the origin of the RPA. Under direct vision, the remaining aorta was then transected and a small cuff of posterior aortic wall around the pulmonary artery origin was excised without compromising the left coronary ostium. Adequate length for a primary end-to-side anastomosis to the MPA was provided. The aortic arch was then mobilized and subsequently reconstructed under no tension.

Correction of patients with *complex* associated anomalies is associated with a high mortality rate (60% at 1 month). Five patients with the aforementioned syndrome of APSD associated with aortic origin of the RPA have been operated on, and the techniques used have been previously described.[44]

In 25 patients, pulmonary arterial pressures were obtained before and after operation. In all patients, irrespective of age and associated anomalies, the right-sided pressures decreased after operation, although not all became normal. The age range at operation among these 25 patients was 5 days to 20 years. Normalization of

TABLE 3. *Operative Procedures and Results*

		Mortality Rate (%)	
Type of Repair	No. of Patients	1 Month	1 Year
Nonanatomic			
PDA ligation	2	50	100

APSD = aortopulmonary septal defect.

pressures after anatomic correction as a function of age was statistically tested and found to be significant using the Student's t-test ($p < 0.02$), and the nonparametric Kolmogorov-Smirnov Two-Sample Test ($p < 0.003$). The trend towards nonnormalization began in patients corrected after 4 months of age.

Follow-up of patients treated surgically ranged from birth to 5 years. Among those who had anatomic correction, all were asymptomatic even though some had persistent pulmonary hypertension. The longest postoperative follow-up study of pulmonary flow was 4 years in a patient who was corrected with a Teflon interposition graft.[21] At that time, pulmonary pressures were found to be normal and flow to lungs was bilateral and symmetrical with a 7-mmHg MPA to RPA gradient. There are no 10-year evaluations in the literature except for one of the patients reported in this study.

Embryology

Although the term "hemitruncus" has frequently been applied to the origin of the RPA from the aorta, it is not accurate since aortopulmonary septation is usually complete and the truncus arteriosus is not persistent. The term implies that the anomalous vessel arises from a common arterial trunk and therefore its use should be discouraged.

The proximal portions of the RPA and LPA arise from the most proximal portions of the sixth aortic arches, which in turn arise from the posterior aspect of the aortic sac. Two different interpretations of these developmental relationships in humans are shown in Figures 6 and 7.[46–48] The sixth aortic arches may arise on opposite sides of the aortic sac.[46] There is a leftward migration of the RPA towards the LPA and the left sixth arch. Alternatively, the RPA and LPA may initially be more closely related. This is followed by a realignment of the RPA toward the MPA, which relates directly to the origin of the LPA (Fig. 8). Sequential events in the development of the aortic arches and pulmonary arteries may be directly imaged in rodent embryos by using a method employing microradiography after microvascular injections of silver nitrate.[49] Aortic arch development in the mouse is analogous to that in humans.[49] In the mouse embryo, the RPA and LPA closely relate to the posterior aspect of the aortic sac (Fig. 8, *left*) and subsequently to the proximal MPA (Fig. 8, *right*). This work supports the earlier studies of Congdon.[47]

Two major hypotheses have been advanced to explain anomalous origin of the RPA from the ascending aorta.[24,31] In the first, origin of the RPA from the aorta is attributed to a "subnormal" migration of the RPA that leaves its origin relating to the aorta after normal truncal septation.[31] Normally, fusion of the truncal ridges results in partitioning of the truncus arteriosus into the aorta and MPA. The truncal malseptation hypothesis[49] attributes anomalous origin of the RPA from the aorta to an asymmetric division of the truncus that leaves the right sixth arch on the "wrong" (aortic) side. Schneiderman[50] attributed the anomaly to faulty timing in the simultaneous events of migration of the RPA and truncal septation.

The accuracy of these competing hypotheses can be determined only by future experimental methods. How-

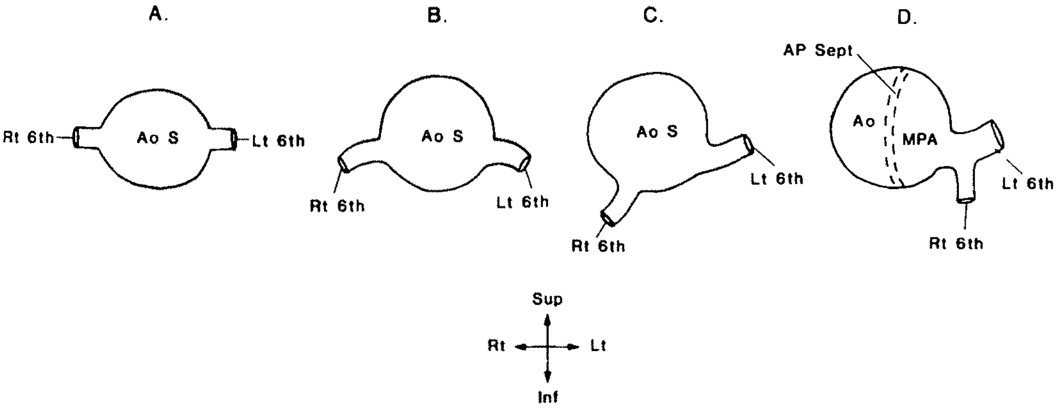

FIG. 6. Development at the pulmonary arteries (redrawn from Orts Llorca original diagrams, 1933, by permission).

ever, several reported experimental embryologic studies are relevant to an understanding of the pathogenesis of this anomaly. In Vitamin A deficient rats the fetus develops a high incidence of defects of the aortopulmonary septum (44%), the ventricular septum, and the aortic arches.[51] Two fetuses were noted to have anomalous origin of the RPA from the ascending aorta. In this 1950 report, the authors speculated that such an anomaly might possibly occur in humans, a prediction that was verified in subsequent case reports. Several workers have noted highly specific cardiovascular teratologic effects when Fertilysin, an oral abortifacient, is administered to rodents. Abnormal origin of the pulmonary artery from distinct aortic and pulmonic trunks was noted in 17 to 163 hamster fetuses examined on the 15th day of gestation after Fertilysin administration on the 8th and 9th days.[52]

Quail-chick chimera experiments have demonstrated that the tunica media and adventitia, but not the endothelium, of the large branchial arch arteries originate from mesoectodermal cells derived from the neural crest.[53] These mesoectodermal cells extend into the arterial outflow portion of the heart and participate in aortopulmonary and conotruncal septation.[53,54] Selective ablation of premigratory neural crest tissue from somites 1 through 5 in chick embryos results in a significant incidence of persistent truncus arteriosus, VSD, and double outlet right ventricle.[55] Previous workers[56] also have demonstrated the importance of a population of extracardiac cells that migrate into the aortopulmonary septum. Recent work strongly suggests that these cells are derived from the neural crest.[54,55] Use of these techniques may prove to specifically identify the developmental abnormalities responsible for the lesion of discussion.

Recent studies on the genetic and hemodynamic aspects of congenital cardiovascular lesions suggest that specific lesions involving the conotruncal portion of the heart frequently coexist with other conotruncal defects[57,58] and that aortic arch anomalies are frequently associated with VSDs.[59] Although coexisting cardiac and extracardiac defects may be produced by alterations in the embryonic hemodynamic factors,[60] the relative importance of genetic and hemodynamic factors in the pathogenesis of specific lesions remains unknown.

Discussion

Patients with origin of the RPA from the ascending aorta usually present during infancy with respiratory distress, failure to thrive, tachycardia, and a heart murmur. Cyanosis occurs in nearly half of these patients. Experimental studies have shown no change in resting arterial saturation unless 85% of the lung is removed. When a pulmonary artery is ligated, oxygen uptake simply doubles on the contralateral side, maintaining adequate oxygenation. The lung on the occluded side decreases its ventilation by bronchoconstriction as a con-

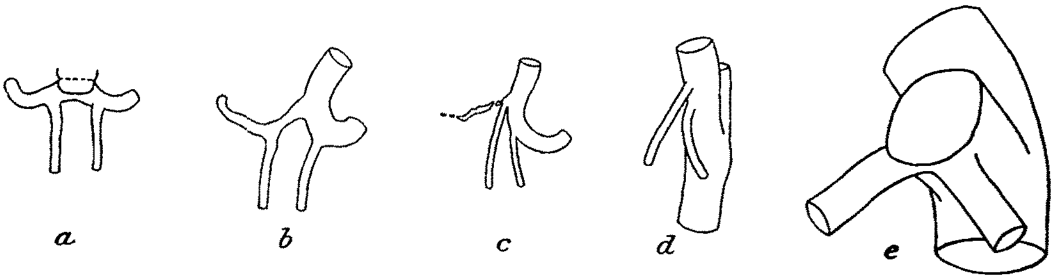

FIG. 7. Development of the pulmonary arteries (Congdon, 1922).

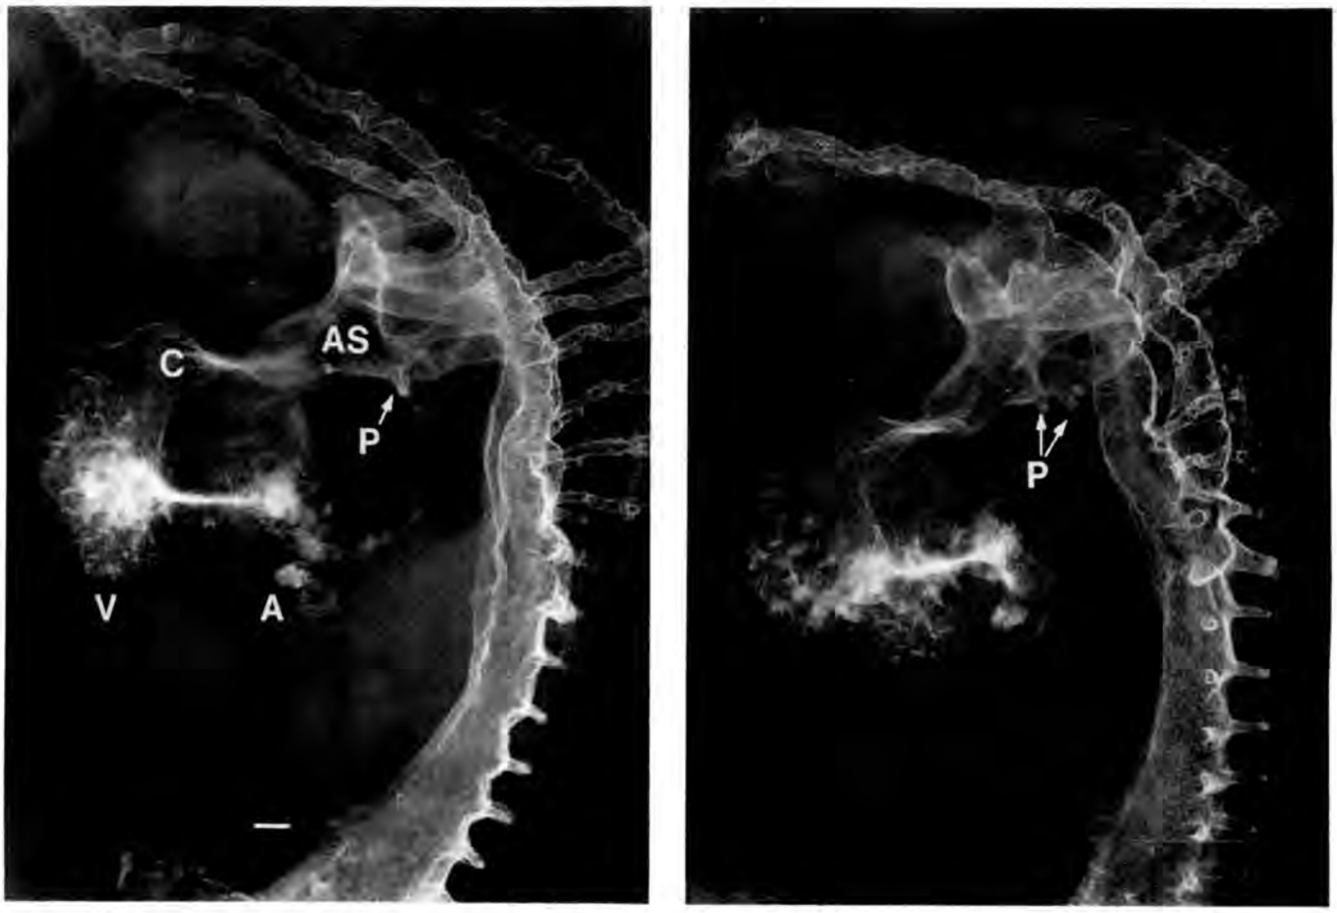

FIG. 8. *Left.* Lateral microradiograph of a mouse embryo at 11.5 days of gestation (6.5 mm crown rump length). *Right.* Left anterior oblique microradiograph of the same. Embryos were prepared and studied by perfusion-fixation with glutaraldehyde through the umbilical vein, retrograde injection of the umbilical artery with 5% silver nitrate, critical point drying, and radiography on high-resolution plates. The method renders the endothelial surface opaque. The line at the bottom equals 0.1 mm (100 μm). These two views demonstrate the close origin of the right and left pulmonary arteries (P) to the posterior aspect of the aortic sac (AS). The conotruncal portion of the arterial outflow (C) is undergoing division. Atria (A) and ventricles (V) connected by narrow atrioventricular canal formed by superior and inferior endocardial cushions.

sequence of alveolar hypocapnea. This explains the reason arterial saturation is normal in these patients unless gas exchange is impaired by pulmonary edema, bronchopneumonia, or right-to-left shunting through an associated anomaly.

Chest films uniformly reveal cardiomegaly, and increased pulmonary vascularity, either bilaterally or on the right side only, is present in all patients and is not influenced by associated anomalies. EKGs are nonspecific with right-sided, left-sided, and biventricular hypertrophy being present and are independent of concomitant lesions. Therefore, a specific diagnosis cannot be made based solely on the history, physical examination, chest film, and EKG.

Other noninvasive techniques have been more successful in establishing a diagnosis of this anomaly as well as associated defects. Suprasternal notch two-dimensional echocardiography is helpful in evaluating the ascending aorta and pulmonary arteries.[30,61-63] Other windows may identify most defects associated with aortic origin of the RPA except for PDA. Using conventional two-dimensional echocardiography, PDA, in general, is not visualized unless it is large, *e.g.*, when there is systemic dependence on its patency.[30] Newer techniques, including standard doppler methods and color-flow doppler, have improved the sensitivity of echocardiography. Magnetic resonance imaging is an excellent noninvasive method for depicting congenital abnormalities of the heart and great vessels, and may provide otherwise unobtainable information.[64] Radionuclide angiography has also been performed in the diagnosis of anomalous origin of the RPA from the ascending aorta.[40]

Experimental studies by Levy and Blalock revealed that pulmonary hypertension did not develop after anastomosis of the left subclavian artery to the LPA.[65] However, Muller et al. were able to induce pulmonary hypertension after anastomosis of the descending aorta to the LPA; at 1 year the degree of hypertension was proportional to the size of the anastomosis.[66] Dammann et al. produced lobar pulmonary hypertension by connecting the LPA to the left upper lobe branch of the pulmonary artery with subsequent development of intimal hyperplasia and medial hypertrophy.[67] Based on these studies, it is believed that the most important determinants of the severity of pulmonary hypertension are size of anastomosis (or connection) and size of the pulmonary vascular bed.

It is interesting to speculate on why pulmonary hypertension occurs on the left side. After a pneumonectomy, 100% of the right ventricular output flows to one lung, yet little increase in pulmonary pressure has been noted up to 11 years.[68,69] In fact, both experimental and clinical studies have indicated that up to 75% reduction in lung volumes does not produce pulmonary hypertension.[70–73] Acute and chronic ligation of a pulmonary artery has also been done in both animals and humans without producing elevated pulmonary pressures.[74–76] Rudolf et al. reported the long-term effects of pneumonectomy or ligation of one pulmonary artery in adult dogs compared with 1- to 2-month-old puppies,[77] and noted moderate progressive increases in pulmonary pressure, which, in a number of animals, showed a tendency towards return to normal. There were greater pressure increases in the puppies, but significant pulmonary hypertension did not develop. In fetal studies, ligation of the ductus arteriosus led to pulmonary hypertension for at least 24 hours.[78] Unilateral ligation of a pulmonary artery caused varying degrees of moderate pulmonary hypertension; however, the study did not continue to postpartem when inflation of the lung results in reduced pulmonary vascular resistance.[79]

The cause of elevated LPA pressure in patients with aortic origin of the RPA is not known. It is postulated that there is a reflex vasoconstriction, or "neurogenic crossover."[30,73] The study of Rudolf et al. of ligation or pneumonectomy was performed in 1–2-month-old puppies. By 8 weeks an "adult"-type pulmonary vasculature has replaced the "fetal" characteristics, defined by lumen-to-wall ratios.[80] It is possible that increased flow may cause pulmonary hypertension when fetal vasculature is present. It is not known whether ligation or pneumonectomy in the neonate produces significant pulmonary hypertension in the contralateral lung. An experimental model that reproduces aortic origin of the RPA and its pathophysiology has not been performed. Irreversible changes of pulmonary hypertension develop on the left side even in patients without left-to-right shunts.

Clearly, anatomic repair of aortic origin of the RPA has led to substantial improvement in survival. The selection of a primary repair *versus* synthetic graft interposition has not affected operative mortality or 1-year survival. Long-term patency of the RPA after either repair is not documented. In fact, before this report, the latest follow-up evaluating pulmonary flow was at 4 years. Our patient required operative intervention because of failure to thrive. He returned to normal growth and is now asymptomatic at 10 years after operation.

The long-term effect of unilateral pulmonary artery occlusion is not known. A related situation may be the congenital malformation of pulmonary artery sling. The currently advocated surgical repair of this lesion is division of the anomalous vessel and primary anastomosis of the proximal LPA to the MPA. Such patients have been studied as long as 24 years after operation.[81] Most survivors remain asymptomatic with no flow through the LPA. Mechanisms of the obstruction to pulmonary blood flow in pulmonary artery sling are believed to be variable with thrombosis and cicatrical stenosis as the most likely causes.[82] Improved patency results have been reported recently and are attributed to advances in microsurgical techniques of primary anastomosis.[83] Attempts to reconstruct the occluded vessels have failed in the past.

Both histopathologic pulmonary vascular changes and physiologic responses to operation are related to the patient's age. All patients in whom pulmonary histology was examined during their first month of life, before surgery, had no pathologic changes. Medial hypertrophy and intimal hyperplasia occur in the setting of increased pulmonary blood flow and are generally considered reversible. Intimal hyperplasia, however, progresses to intimal fibrosis with continued insult. The current review shows simultaneous onset of both medial hypertrophy and intimal hyperplasia as early as 1 month of age. Intimal fibrosis has been seen as early as 1–2 months. All those in whom correction was performed within 1 month of life normalized their pulmonary artery pressures after operation. Non-normalization of pulmonary pressures after correction has occurred in patients as young as 4 months and increases in proportion to patient age. It is interesting that non-normalization of pressures occurred in patients considered to have reversible histopathologic changes. This may be related to an inadequate follow-up to allow full regression of these changes. Theoretically, associated anomalies that increase pulmonary blood flow should accelerate the process of histopathologic changes. However, no statistical correlation was evident in this review.

The developmental error responsible for anomalous origin of the RPA is unclear. With the high incidence of aortopulmonary septal abnormalities associated with this lesion, the malseptation hypothesis is attractive. Teratogenic studies, which have produced arch defects, may prove useful in differentiating among the various hypotheses in the future.

Tumor Markers and Tumor-Associated Antigens. Bimal C. Ghosh, Luna Ghosh. 343 pp. New York: McGraw-Hill Book Co. 1987. $59.50.

THIS BOOK PROVIDES current information about tumor markers and is directed toward students and professionals engaged in cancer research and treatment. Drs. Bimal and Luna Ghosh have co-edited a good reference text on the subject that will be of value to those interested in the field. The book describes the current state of knowledge involving the characterization of tumor markers and tumor-associated antigens for all aspects of human cancer. It also describes the use of various reagents to detect these markers in cancer patients and their clinical significance in diagnosis, prognosis, and treatment. Some of the best chapters include those describing the use of carcinoembryonic antigen (58 references), tumor markers in pancreatic tumors (97 references), breast cancer (61 references), melanoma (63 references), soft tissue sarcomas (58 references), endocrine tumors (112 references), lymphomas and leukemias (99 references), and the use of the monoclonal antibodies in immunopathology (124 references). The last chapter also includes a useful appendix describing the immunoperoxidase technique, which is an important tool for detecting tumor markers and tumor-associated antigens in tissue sections. The book is well organized, easy to follow, and contains a comprehensive reference list at the conclusion of each chapter. The only limitation of such a book is the rapid pace of this scientific field and the burgeoning number of markers and antigens that are described in the literature each month. Nevertheless, this book provides a good baseline describing current knowledge in this field and should be useful to anyone who is interested in this important area of scientific and clinical investigation.

CHARLES M. BALCH, M.D.
Houston, Texas

Anesthesia and Uncommon Pediatric Diseases. Jordan Katz, David J. Steward. 560 pp. Philadelphia: W.B. Saunders Co. 1987. $65.00.

THIS TEXT is a comprehensive review of many common and uncommon diseases of infancy and childhood that have an impact on anesthetic and surgical practice. In this book Drs. Katz and Steward, together with 21 contributing authors, all recognized experts in the field of pediatric anesthesia, provide the scientific basis and the clinical knowledge requisite for the medical and anesthetic management of each disease.

In general, the text is well organized, reviewing all aspects of childhood illnesses to be encountered in the perioperative period. The distinctive hallmark of this text is the integration of pathophysiologic principles with clinical experience and practice. The book begins with chapters on anatomy, physiology, and pharmacology with specific reference to the special differences in children when compared with adults. The second section of the text deals with disease states of the major organ systems. It includes detailed discussion of the various childhood diseases of the central nervous system, respiratory system, cardiovascular system, renal system, and gastrointestinal system. The remainder of the text reviews childhood diseases as they relate to anatomic approaches, *e.g.,* head and neck syndromes, opthalmologic, otolaryngologic, or systemic diseases (hematologic, metabolic, and infectious illnesses). Within each chapter the pathophysiology is discussed in detail as well as the surgical procedure and anesthetic implications.

The weaknesses of the book are that some chapters are too wordy and lengthy. A second minor criticism is that most of the material can be found in other texts, albeit not as consolidated as this text. This book is not for the generalist. It contains highly specialized material as it relates to diseases of children and it is aimed at the instruction of physicians who deal intensively with the pediatric patient. This text is especially recommended for those physicians whose clinical practice of medicine depends heavily on the knowledge of childhood disease states, operative procedures, and subsequent anesthetic management.

In the preface Drs. Katz and Steward state "We have attempted to assemble more than a simple book of anesthesia-related facts and have designed this volume to provide a detailed summary backed by knowledge which related to each disease." I believe this text admirably accomplishes this intention. Surgeons, anesthesiologists, and intensive care providers involved in the care of children will find this text an invaluable resource and the supplement of major texts.

New for 1987

For your professional library
Bound volumes of
Annals of Surgery

Long after your personal copies of ANNALS OF SURGERY have been read, shared with your office staff, used up and worn out, you can have instant access to the unique and valuable information in back issues of this distinguished journal by ordering bound volumes.

Your bound volumes give you a permanent and comprehensive reference for changes and advances in your specialty—a source that will grow and increase in usefulness over the years. Each volume features:

- *all text pages of every issue, including the complete author and title indexes*
- *no advertising—only professional, clinically pertinent material (a space-saver on your bookshelves)*
- *handsome, durable bindings in maroon buckram, with the journal name, year, and volume number imprinted in gold on the spine*

No need to return your personal copies to us, or to go to the trouble and expense of having them bound locally. We over-run copies of each issue in order to have sufficient quantities on hand. But we must tell our printer how many we need, so please let us know right away.

You must be a current subscriber to take advantage of this bound volume offer.

Use the convenient coupon to order your 1987 volumes today. They will be on their way to you shortly after the publication of the final volume issue.

Yes! Please send me the 1987 bound volumes of ANNALS OF SURGERY (65-98635/65-98643) for $49.00 U.S. ($59.00 elsewhere).

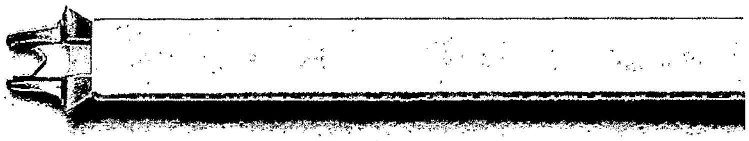
We've Corrected Everybody's Flaws. Even Our Own.

And now Weck is ready with the Hemoclip® X20. The first ring-handled automatic ligating clip applier that's as close to perfect as you can get.

But during development, we corrected a lot of flaws we found in competitive disposables, and even in our own first-stage X20 prototype.



Here's the result: the X20's long straight shaft, curved tip and jaws

provide smooth, accurate placement. Jaws are always visible, and they don't retract or jump forward during closure.

There's no cocking a feeder, because the new X20 with clip counter is fully automatic. This truly one-handed disposable virtually eliminates dropped clips.

Contact your Weck representative, and free up some hands in the OR.

The Hemoclip® X20.
The Perfect Way To Apply
A Hemoclip® Clip.

WECK®

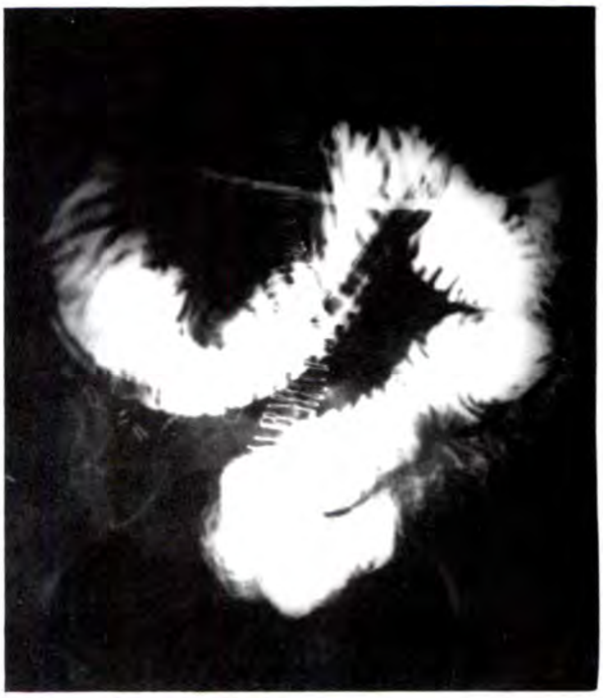
CASE # 24 **AGE:** 55 **SEX:** FEMALE
DIAGNOSIS: CECAL CARCINOMA
SYMPTOMS: ANEMIA (Hg 6 gm/dl)
OPERATION: RIGHT HEMICOLECTOMY & GASTROSTOMY

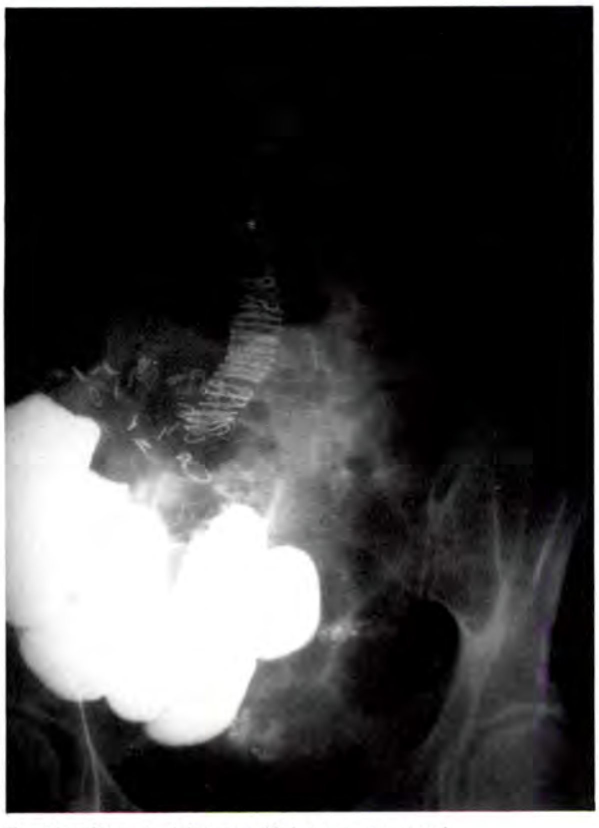
The patient had a right hemicolectomy with stapled (U.S. Surgical Corp) anastomosis and fascia closure and a MOSS® gastrostomy tube. The stomach and proximal duodenum were aspirated, with immediate simultaneous feeding into the distal duodenum.

Barium feeding 5 hours postop documented adequate motility. The deliberate excess was totally removed. No contrast (i.e.: excess feeding) escaped efficient aspiration within the proximal duodenum, to reflux into the stomach. (Figure A) Serial motility study showed barium had traversed the anastomosis and colon, and already was exiting in a spontaneous bowel movement by 21 hours postop. (Figure C)

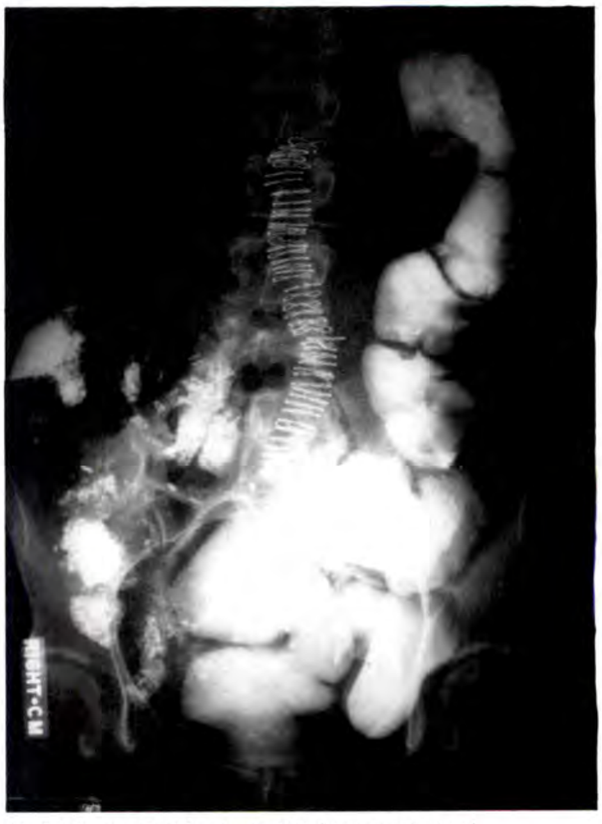
She received 300 ml/hr of Vivonex TEN (Norwich Eaton Pharm), absorbed 5,000 kcal the initial 20 hours, and then tolerated a general diet. She was the 4th patient discharged uneventfully 24 hours after bowel resection and reanastomosis.



A. Study @ 5 minutes (5 hours postop).
Note efficient removal of all excess barium, with none reaching the stomach.



B. Motility @ 4 hours (9 hours postop).
All barium is within the ileum.



C. Motility @ 16 hours (21 hours postop).
Barium is exiting in a spontaneous bowel movement.

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

CEFOTAN® (cefotetan disodium)

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)

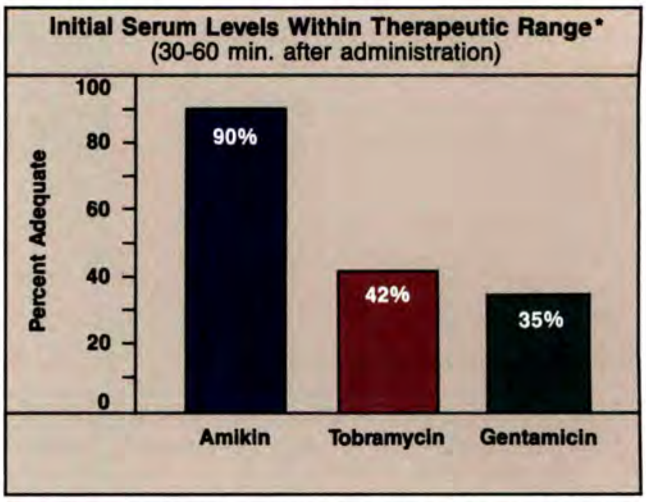
IN EMPIRIC THERAPY OF
NOSOCOMIAL INFECTIONS

Peace of mind. Right from the start.

When infection develops in the hospitalized patient, there's no time to be wrong. Amikin® (amikacin sulfate) delivers the aggressive First-Dose therapy that can save lives.

First-Dose Predictability.
After the first dose, Amikin produces therapeutic blood levels that are more predictable than those of the other aminoglycosides.[1]

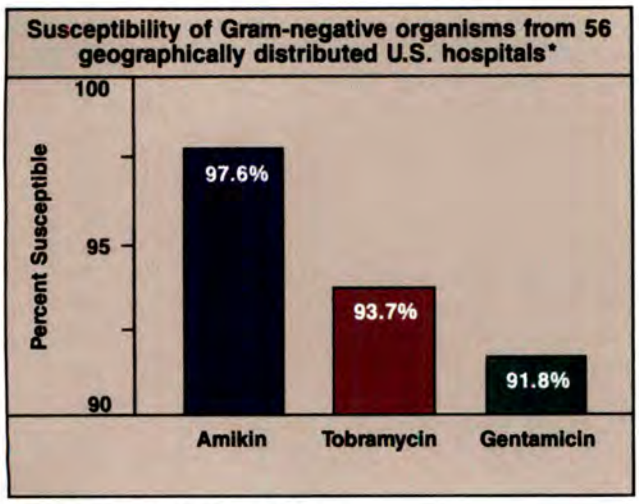


*Adapted from Holloway WJ: Management of sepsis in the elderly. *Am J Med* 80 (suppl 6B): 143-148, 1986.

BRISTOL®
NDC 0015-3020-20
Amikin®
AMIKACIN SULFATE
INJECTION For I.M. or I.V. Use
EQUIVALENT TO
500 mg AMIKACIN Per 2 ml
CAUTION: Federal law prohibits dispensing without prescription.
20
30
40

First-Dose Antimicrobial Activity.

Amikin has the broadest spectrum of any aminoglycoside.[2]



Total Amikin isolates = 247,503

*In vitro data may not be directly correlated to clinical effectiveness. Data on file, Bristol Laboratories.

First-Dose Synergy.

In combination with antipseudomonal penicillins and latest generation cephalosporins, Amikin is overall the most synergistic of the aminoglycosides.[3,4]

First-Dose Economy.

The least expensive aminoglycoside is not necessarily the one with the lowest acquisition cost. It's the one *not* requiring replacement with a more effective agent.[5]

AMIKIN®

AMIKACIN SULFATE

BRIEF SUMMARY OF PRESCRIBING INFORMATION (1) 10/83
For complete prescribing information, please consult product literature.

WARNINGS

Patients treated with aminoglycosides should be under close clinical observation because of the potential ototoxicity and nephrotoxicity associated with their use.

Ototoxicity, both auditory and vestibular, can occur in patients treated at higher doses or for periods longer than those recommended. The risk of amikacin-induced ototoxicity is greater in patients with renal damage. High frequency deafness usually occurs first and can be detected only by audiometric testing. Vertigo may occur and may be evidence of vestibular injury.

The ototoxicity potential of amikacin in infants is not known. Until more safety reports become available, amikacin should be used in infants only in those specific circumstances when susceptibility testing indicates that other aminoglycosides cannot be used or are otherwise contraindicated, and when the infant can be observed closely for evidence of toxicity.

Aminoglycosides are potentially nephrotoxic. Renal and eighth-nerve function should be closely monitored in patients with known or suspected renal impairment and also in those whose renal function is initially normal but who develop signs of renal dysfunction during therapy. Such impairment may be characterized by decreased creatinine clearance, the presence of cells or casts, oliguria, proteinuria, decreased urine specific gravity or evidence of increasing nitrogen retention (increasing BUN or creatinine).

Evidence of impairment in renal, vestibular or auditory function requires discontinuation of the drug or dosage adjustment.

Serum concentrations should be monitored when feasible, and prolonged peak concentrations above 35 mcg/ml should be avoided. Urine should be examined for increased excretion of protein, the presence of cells and casts, and decreased specific gravity.

Concurrent and/or sequential use of topically or systemically neurotoxic or nephrotoxic antibiotics, particularly kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin should be avoided.

AMIKIN should not be given concurrently with potent diuretics (ethacrynic acid, furosemide, meralluride sodium, sodium mercaptomerin or mannitol). Some diuretics themselves cause ototoxicity, and intravenously administered diuretics enhance aminoglycoside toxicity by altering antibiotic concentrations in serum and tissue.

CONTRAINDICATIONS

A history of hypersensitivity to amikacin is a contraindication for its use.

WARNINGS

See "Warning" box above.

PRECAUTIONS

AMIKIN is potentially nephrotoxic, ototoxic, and neurotoxic. The concurrent or serial use of other ototoxic or nephrotoxic agents should be avoided either systemically or topically because of the potential for additive effects. Such agents include antibacterial drugs such as kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin as well as certain diuretic agents such as ethacrynic acid or furosemide.

Ototoxicity — See "Warning" box.

Nephrotoxicity — Since AMIKIN is present in high concentrations in the renal excretory system, patients should be well hydrated to minimize chemical irritation of the renal tubules. Kidney function should be assessed by the usual methods prior to starting therapy and daily during the course of treatment.

If signs of renal irritation appear (casts, white or red cells or albumin), hydration should be increased. A reduction in dosage (see "Dosage and Administration") may be desirable if other evidence of renal dysfunction occurs such as decreased creatinine clearance, decreased urine specific gravity, increased BUN, creatinine or oliguria. If azotemia increases or if a progressive decrease in urinary output occurs, treatment should be stopped.

Note: When patients are well hydrated and kidney function is normal the risk of nephrotoxic reactions with amikacin is low if the dosage recommendations (see "Dosage and Administration") are not exceeded.

Neurotoxicity — Neuromuscular blockade and muscular paralysis have been demonstrated in the cat with high doses of amikacin (188 mg/Kg). The possibility of neuromuscular blockade and respiratory paralysis should be considered when amikacin is administered concomitantly with anesthetic or neuromuscular blocking drugs. If blockade occurs, calcium salts may reverse this phenomenon.

Other — Cross-allergenicity among aminoglycosides has been demonstrated. As with other antibiotics the use of amikacin may result in overgrowth of nonsusceptible organisms. If this occurs, appropriate therapy should be instituted.

Pregnancy — Reproduction studies have been performed in rats and mice and have revealed no evidence of impaired fertility or harm to the fetus due to amikacin. There are no well-controlled studies in pregnant women but investigational experience does not include any positive evidence of adverse effects on the fetus. Although there is no clearly defined risk, such experience cannot exclude the possibility of infrequent or subtle damage to the fetus. AMIKIN should be used in pregnant women only when clearly needed.

It is not known whether this drug is excreted in human milk. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

ADVERSE REACTIONS

Ototoxicity — See "Warning" box.

Nephrotoxicity — Albuminuria, presence of red and white cells, casts, azotemia and oliguria have been reported.

Other — In addition to those described above, other adverse reactions which have been reported on rare occasions are skin rash, drug fever, headache, paresthesia, tremor, nausea and vomiting, eosinophilia, arthralgia, anemia, hypotension.

Overdosage — In the event of overdosage or toxic reaction, peritoneal dialysis or hemodialysis will aid in the removal of amikacin from the blood.

We've Corrected Everybody's Flaws. Even Our Own.

And now Weck is ready with the Hemoclip® X20. The first ring-handled automatic ligating clip applier that's as close to perfect as you can get.

But during development, we corrected a lot of flaws we found in competitive disposables, and

even in our own first-stage X20 prototype.

Here's the result: the X20's long straight shaft, curved tip and jaws

provide smooth, accurate placement. Jaws are always visible, and they don't retract or jump forward during closure.

There's no cocking a feeder, because the new X20 with clip counter is fully automatic. This truly one-handed disposable virtually eliminates dropped clips.

Contact your Weck representative, and free up some hands in the OR.

The Hemoclip® X20.
The Perfect Way To Apply
A Hemoclip® Clip.

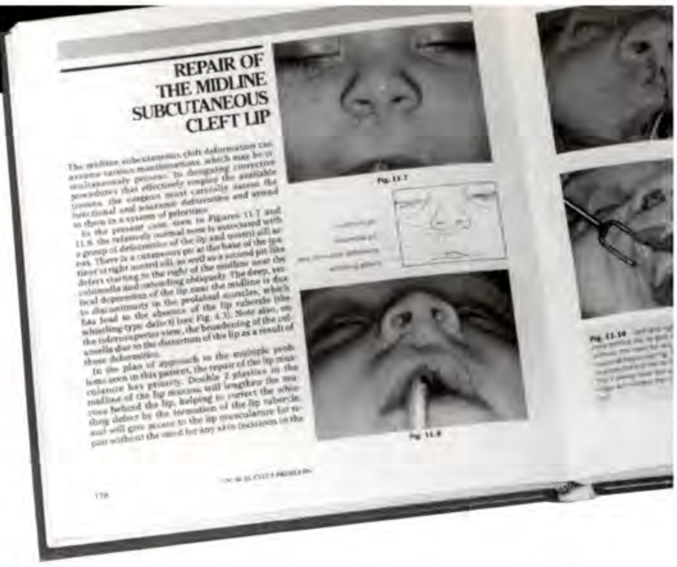
A VIVID, FULL COLOR ATLAS...



Techniques in CLEFT LIP, NOSE AND PALATE RECONSTRUCTION

...show you the art of reconstructive plastic surgery for children born with cleft deformities

By Donald I. Kapetansky, M.D.

Foreword by D. Ralph Millard, Jr., M.D.

250 Beautiful, full-color illustrations...

. . . show you some of the most effective and efficient procedures in use today to correct cleft deformities in children. Sequential photographs of operations show each step of repair. Clear, close-up photographs show cleft deformities from various angles to help you fully understand the patient's condition. Detailed line drawings, full-color schematic diagrams, and explanatory text accompany the photographs and clarify important aspects of the deformities and the surgical techniques employed to correct them.

Complete coverage of surgical procedures

This book is divided into four parts, each focusing on a particular type of congenital deformity. Parts I and II focus, respectively, on primary and deferred corrective procedures for unilateral and bilateral cleft lip and nose reconstruction. These sections are primarily concerned with improving the child's appearance. Part III deals with cleft palate reconstruction and pharyngeal-flap procedures. This section details surgical techniques aimed at restoring the function of the palate in speech production—without producing iatrogenic facial deformities. Two types of transverse pharyngeal-flap surgery are described in this section. Part IV deals with some unusual cleft problems and three case studies in long-term cleft reconstruction.

Considers the total perioperative picture

With 25 years of practice and more than 2500 cleft operations to his credit, the author brings a wide range of experience and an authoritative viewpoint to this work. From a concentration on techniques that require fewer staged procedures, to methods of suturing the skin, to the use of long-acting local anesthetics even with general anesthesia—you'll find a multitude of suggestions for pre- and postoperative care and interoperative planning that aim to ease the strain on children enduring multiple surgical procedures.

Lippincott

following surgery for primary breast cancer..
What next?

Until now,

there has been no definitive treatment for stage II postmenopausal patients…

Chemotherapy

Contribution of cytotoxics uncertain; potentially serious/intolerable side effects

No therapy

Important new data[1] rule out no therapy

Today there is.

Nolvadex® 10 MG TABLETS
TAMOXIFEN CITRATE
Adjuvant Monotherapy

Now, the treatment of choice

A recent National Institutes of Health consensus report states that following surgery, "Tamoxifen [NOLVADEX] should now be regarded as standard therapy for postmenopausal patients with positive axillary lymph nodes and positive hormone receptor status."[1]

NOLVADEX increases disease-free time[2-5] by delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer ($T_{1\text{-}3}$, N_1, M_0). Moreover, NOLVADEX improves overall survival, with a 34% reduction in risk of mortality, as observed in the NOLVADEX Adjuvant Trial Organization (NATO) study.[4] This treatment is extremely well tolerated by patients[2-5]; in fact, one double-blind, placebo-controlled study demonstrated a NOLVADEX side effects profile similar to placebo.[2] And, since NOLVADEX has a mild side effects profile and is easy to administer, patients are afforded a better quality of life. NOLVADEX—today's promising breast cancer therapy for the postmenopausal woman—in the adjuvant setting and in metastatic disease.

Please see next page for brief summary of prescribing information.

STUART PHARMACEUTICALS
Division of ICI Americas Inc
Wilmington, Delaware 19897

Nolvadex® 10 MG TABLETS
TAMOXIFEN CITRATE

BRIEF SUMMARY

INDICATIONS AND USAGE: NOLVADEX is effective in the treatment of metastatic breast cancer in postmenopausal women. Available evidence indicates that patients whose tumors are estrogen receptor positive are more likely to benefit from NOLVADEX therapy.

NOLVADEX is effective in delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T1-3, N1, M0). The estrogen and progesterone receptor values may help to predict whether NOLVADEX therapy is likely to be beneficial. In some NOLVADEX adjuvant studies, most of the benefit to date has been in the subgroup with 4 or more positive axillary nodes.

CONTRAINDICATIONS: None known.

WARNINGS: Pregnancy Category D: NOLVADEX may cause fetal harm when administered to a pregnant woman. Individuals should not become pregnant while taking NOLVADEX. Effects on reproductive functions are expected from the antiestrogenic properties of the drug. In reproductive studies in rats at dose levels equal to or below the human dose, nonteratogenic developmental skeletal changes were seen and were found to be reversible. In addition, in fertility studies in rats and in teratology studies in rabbits using doses at or below those used in humans, a lower incidence of embryo implantation and a higher incidence of fetal death or retarded in utero growth were observed, with slower learning behavior in some rat pups. The impairment of learning behavior did not achieve statistical significance in one study, and, in another study where significance was reported, this was by comparing dosed animals with controls of another study. Several pregnant marmosets were dosed during organogenesis or in the last half of pregnancy. No deformations were seen and although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. There are no adequate and well controlled studies in pregnant women. There have been reports of spontaneous abortions, birth defects, fetal deaths, and vaginal bleeding. If this drug is used during pregnancy or the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Ocular changes have been reported in a few patients who, as part of a clinical trial, were treated for periods greater than one year with NOLVADEX at doses at least four times the highest recommended daily dose of 40 mg. The ocular changes consist of retinopathy and, in some patients, there are also corneal changes and a decrease in visual acuity.

In addition, a few cases of ocular changes including visual disturbance, corneal changes, and/or retinopathy have been reported in patients treated with NOLVADEX at recommended doses. It is uncertain if these effects are due to NOLVADEX.

As with other additive hormonal therapy (estrogens and androgens), hypercalcemia has been reported in some breast cancer patients with bone metastasis within a few weeks of starting treatment with NOLVADEX. If hypercalcemia does occur, appropriate measures should be taken and, if severe, NOLVADEX should be discontinued.

PRECAUTIONS: General: NOLVADEX should be used cautiously in patients with existing leukopenia or thrombocytopenia. Observations of leukopenia and thrombocytopenia occasionally have been made, but it is uncertain if these effects are due to NOLVADEX therapy. Transient decreases in platelet counts, usually to 50,000-100,000/cu mm, infrequently lower, have been occasionally reported in patients taking NOLVADEX for breast cancer. No hemorrhagic tendency has been recorded and the platelet counts returned to normal levels even though treatment with NOLVADEX continued.

Laboratory Tests: Periodic complete blood counts, including platelet counts, may be appropriate.

Carcinogenesis: While no conventional bioassay has been conducted, endocrine changes in immature and mature mice were investigated in a 13-month study. Granulosa cell ovarian tumors and interstitial cell testicular tumors were found in mice receiving NOLVADEX, but not in the controls.

Mutagenesis: No genotoxic potential has been found in a battery of in vivo and in vitro tests with pro- and eukaryotic test systems with drug metabolizing systems present.

Impairment of Fertility: Fertility in female rats was decreased following administration of 0.04 mg/kg for 2 weeks prior to mating through day 7 of pregnancy. There was a decreased number of implantations, and all fetuses were found dead.

Following administration to rats of 0.16 mg/kg from days 7-17 of pregnancy, there were increased numbers of fetal deaths. Administration of 0.125 mg/kg to rabbits during days 6-18 of pregnancy resulted in abortion or premature delivery. Fetal deaths occurred at higher doses. There were no teratogenic changes in either rat or rabbit segment II studies. Several pregnant marmosets were dosed with 10 mg/kg/day either during organogenesis or in the last half of pregnancy. No deformations were seen, and, although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. Rats given 0.16 mg/kg from day 17 of pregnancy to 1 day before weaning demonstrated increased numbers of dead pups at parturition. It was reported that some rat pups showed slower learning behavior, but this did not achieve statistical significance in one study, and in another study where significance was reported, this was by comparing dosed animals with controls of another study.

The recommended daily human dose of 20-40 mg corresponds to 0.4-0.8 mg/kg for an average 50 kg woman.

Pregnancy Category D: See WARNINGS.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from NOLVADEX, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

ADVERSE REACTIONS: The most frequent adverse reactions to NOLVADEX are hot flashes, nausea and vomiting. These may occur in up to one fourth of patients, but are rarely severe enough to require discontinuation of treatment.

Less frequently reported adverse reactions are vaginal bleeding, vaginal discharge, menstrual irregularities and skin rash. Usually these have not been of sufficient severity to require dosage reduction or discontinuation of treatment.

Increased bone and tumor pain and, also, local disease flare have occurred, which are sometimes associated with a good tumor response. Patients with increased bone pain may require additional analgesics. Patients with soft tissue disease may have sudden increases in the size of preexisting lesions, sometimes associated with marked erythema within and surrounding the lesions and/or the development of new lesions. When they occur, the bone pain or disease flare are seen shortly after starting NOLVADEX and generally subside rapidly.

Other adverse reactions which are seen infrequently are hypercalcemia, peripheral edema, distaste for food, pruritus vulvae, depression, dizziness, light-headedness and headache. There have been infrequent reports of thromboembolic events occurring during NOLVADEX therapy. Since for cancer patients in general an increased incidence of thromboembolic events is known to occur, a causal relationship to NOLVADEX remains conjectural. An increased incidence has been reported when cytotoxins are combined with NOLVADEX.

If adverse reactions are severe, it is sometimes possible to control them by a simple reduction of dosage without loss of control of the disease.

OVERDOSAGE: Acute overdosage in humans has not been reported. Signs observed at the highest doses following studies to determine LD$_{50}$ in animals were respiratory difficulties and convulsions. No specific treatment for overdosage is known; treatment must be symptomatic.

DOSAGE AND ADMINISTRATION: One or two 10 mg tablets twice a day (morning and evening). In the three single agent adjuvant NOLVADEX studies noted above (See Clinical Pharmacology), NOLVADEX was administered for two years. The optimal duration of adjuvant therapy is not known.

HOW SUPPLIED: Tablets containing tamoxifen as the citrate in an amount equivalent to 10 mg of tamoxifen (round, biconvex, uncoated, white tablet identified with NOLVADEX 600 debossed on one side and a cameo debossed on the other side) are supplied in bottles of 60 tablets and 250 tablets. Protect from heat and light.

WE HAVE ONLY GOOD THINGS TO SAY ABOUT CANCER OF THE COLON.

If detected early, the cure rate for colorectal cancer is very high.

It can be as high as 75%.

Because we now know how to detect it early. And we know how to fight it once we detect it.

There are three simple checkup guidelines for men and women without symptoms.

One, get a digital exam every year. This is recommended for everyone over 40.

Two, get a stool blood test every year if you are over 50.

Three, after two initial negative tests one year apart, get a procto exam every three to five years if you are over 50.

These guidelines are the best protection against colorectal cancer you can have.

If you're not over 50, please give this information to friends and loved ones who are.

In any case, please help spread the word.

Good news doesn't always travel fast.

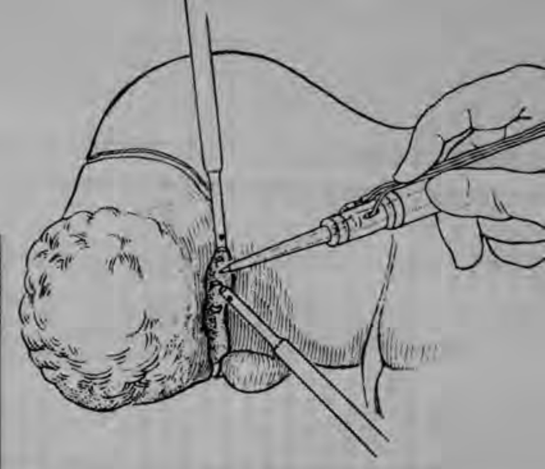
Letters to the Editor

Now...the new book that shows you the role of surgical resection in the curative treatment of metastatic cancer



SURGICAL TREATMENT of METASTATIC CANCER

Edited by Steven A. Rosenberg, M.D., Ph.D.

Chief of Surgery, National Cancer Institute, Bethesda, MD.
9 contributors.

> *For many patients with isolated visceral metastases from solid tumors, surgical resection of those metastatic deposits represents the best opportunity for cure. For patients with solitary pulmonary and hepatic metastases, up to 30% of patients may experience prolonged disease-free survival after metastasectomy. Only a small subset of patients with metastatic cancer are likely to benefit from surgical resection and identification of these patients is an important part of the application of this treatment.*
>
> **—from the *Preface***

Taking a bold approach to treatment

Now, for the first time, here is an in-depth resource that describes the role of surgical resection in the treatment of metastatic cancer. Editor Dr. Steven A. Rosenberg, Chief of Surgery at the National Cancer Institute, and a leading figure in cancer research and treatment, poses the premise that the role of surgical resection in treating metastatic cancer has indeed been underappreciated. He and a distinguished group of contributors have designed this book to present the essential information oncologists and surgeons need to understand the value of this treatment.

Presenting a highly significant option

Detailed information is presented concerning:

- the modern understanding of the biology of the metastatic process
- up-to-date techniques for the diagnosis of lung, liver, and brain metastases
- indications for and results of the surgical resection of lung, liver, and brain metastases
- the indications for lymph node dissection in the treatment of cancer.

NUBAIN
nalbuphine HCl

Brief Summary of Prescribing Information

INDICATIONS For the relief of moderate to severe pain. NUBAIN can also be used for preoperative analgesia, as a supplement to surgical anesthesia, and for obstetrical analgesia during labor.

CONTRAINDICATIONS NUBAIN should not be administered to patients who are hypersensitive to it.

WARNINGS Drug Dependence NUBAIN has been shown to have a low abuse potential which is approximate to that of pentazocine. When compared with drugs which are not mixed agonist-antagonists, it has been reported that nalbuphine's potential for abuse would be less than that of codeine and propoxyphene. Psychological and physical dependence and tolerance may follow the abuse or misuse of nalbuphine. Therefore, caution should be observed in prescribing it for emotionally unstable patients, or for individuals with a history of narcotic abuse. Such patients should be closely supervised when long-term therapy is contemplated. Care should be taken to avoid increases in dosage or frequency of administration which in susceptible individuals might result in physical dependence. Abrupt discontinuation of NUBAIN following prolonged use has been followed by symptoms of narcotic withdrawal, i.e., abdominal cramps, nausea and vomiting, rhinorrhea, lacrimation, restlessness, anxiety, elevated temperature and piloerection. **Use in Ambulatory Patients** NUBAIN may impair the mental or physical abilities required for the performance of potentially dangerous tasks such as driving a car or operating machinery. Therefore, NUBAIN should be administered with caution to ambulatory patients who should be warned to avoid such hazards. **Use in Emergency Procedures** Maintain patient under observation until recovered from NUBAIN effects that would affect driving or other potentially dangerous tasks. **Use in Children** Clinical experience to support administration to patients under 18 years is not available at present. **Use in Pregnancy (other than labor)** Safe use of NUBAIN in pregnancy has not been established. Although animal reproductive studies have not revealed teratogenic or embryotoxic effects, nalbuphine should only be administered to pregnant women when, in the judgement of the physician, the potential benefits outweigh the possible hazards. **Use During Labor and Delivery** NUBAIN can produce respiratory depression in the neonate. It should be used with caution in women delivering premature infants. **Head Injury and Increased Intracranial Pressure** The possible respiratory depressant effects and the potential of potent analgesics to elevate cerebrospinal fluid pressure (resulting from vasodilation following CO_2 retention) may be markedly exaggerated in the presence of head injury, intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, potent analgesics can produce effects which may obscure the clinical course of patients with head injuries. Therefore, NUBAIN should be used in these circumstances only when essential, and then should be administered with extreme caution. **Interaction With Other Central Nervous System Depressants** Although NUBAIN possesses narcotic antagonist activity, there is evidence that in nondependent patients it will not antagonize a narcotic analgesic administered just before, concurrently, or just after an injection of NUBAIN. Therefore, patients receiving a narcotic analgesic, general anesthetics, phenothiazines, or other tranquilizers, sedatives, hypnotics, or other CNS depressants (including alcohol) concomitantly with NUBAIN may exhibit an additive effect. When such combined therapy is contemplated, the dose of one or both agents should be reduced. **Sulfites Sensitivity** NUBAIN contains sodium metabisulfite, a sulfite that may cause allergic-type reactions (e.g., hives, itching, wheezing, anaphylaxis) in certain susceptible persons. Although the overall prevalence of sulfite sensitivity in the general population is probably low, it is seen more frequently in asthmatics or in atopic nonasthmatic persons.

PRECAUTIONS Impaired Respiration At the usual adult dose of 10 mg/70 kg, NUBAIN causes some respiratory depression approximately equal to that produced by equal doses of morphine. However, in contrast to morphine, respiratory depression is not appreciably increased with higher doses of NUBAIN. Respiratory depression induced by NUBAIN can be reversed by NARCAN® (naloxone hydrochloride) when indicated. NUBAIN should be administered with caution at low doses to patients with impaired respiration (e.g., from other medication, uremia, bronchial asthma, severe infection, cyanosis or respiratory obstructions). **Impaired Renal or Hepatic Function** Because NUBAIN is metabolized in the liver and excreted by the kidneys, patients with renal or liver dysfunction may overreact to customary doses. Therefore, in these individuals, NUBAIN should be used with caution and administered in reduced amounts. **Myocardial Infarction** As with all potent analgesics, NUBAIN should be used with caution in patients with myocardial infarction who have nausea or vomiting. **Biliary Tract Surgery** As with all narcotic analgesics, NUBAIN should be used with caution in patients about to undergo surgery of the biliary tract since it may cause spasm of the sphincter of Oddi.

ADVERSE REACTIONS The most frequent adverse reaction in 1066 patients treated with NUBAIN is sedation 381 (36%). Less frequent reactions are sweaty/clammy 99 (9%); nausea/vomiting 68 (6%); dizziness/vertigo 58 (5%); dry mouth 44 (4%); and headache 27 (3%). Other adverse reactions which may occur (reported incidence of 1% or less) are: **CNS Effects** Nervousness, depression, restlessness, crying, euphoria, floating, hostility, unusual dreams, confusion, faintness, hallucinations, dysphoria, feeling of heaviness, numbness, tingling, unreality. The incidence of psychotomimetic effects, such as unreality, depersonalization, delusions, dysphoria and hallucinations has been shown to be less than that which occurs with pentazocine. **Cardiovascular** Hypertension, hypotension, bradycardia, tachycardia. **Gastrointestinal** Cramps, dyspepsia, bitter taste. **Respiration** Depression, dyspnea, asthma. **Dermatological** Itching, burning, urticaria. **Miscellaneous** Speech difficulty, urinary urgency, blurred vision, flushing and warmth. **Patients Dependent on Narcotics** Patients who have been taking narcotics chronically may experience withdrawal symptoms upon the administration of NUBAIN. If unduly troublesome, narcotic withdrawal symptoms can be controlled by the slow intravenous administration of small increments of morphine, until relief occurs. If the previous analgesic was morphine, meperidine, codeine, or other narcotic with similar duration of activity, one-fourth of the anticipated dose of NUBAIN can be administered initially and the patient observed for signs of withdrawal, i.e., abdominal cramps, nausea and vomiting, lacrimation, rhinorrhea, anxiety, restlessness, elevation of temperature or piloerection. If untoward symptoms do not occur, progressively larger doses may be tried at appropriate intervals until the desired level of analgesia is obtained with NUBAIN. **Management of Overdosage** The immediate intravenous administration of NARCAN® (naloxone hydrochloride) is a specific antidote. Oxygen, intravenous fluids, vasopressors and other supportive measures should be used as indicated. The administration of single doses of 72 mg of NUBAIN subcutaneously to eight normal subjects has been reported to have resulted primarily in symptoms of sleepiness and mild dysphoria.

Malignant Carcinoid Tumors

An Analysis of 103 Patients with Regard to Tumor Localization, Hormone Production, and Survival

INGRID NORHEIM, M.D.,[*] KJELL ÖBERG, M.D.,[*] ELVAR THEODORSSON-NORHEIM, M.D.,[†]
PER GUNNAR LINDGREN, M.D.,[‡] GUDMAR LUNDQVIST, M.D.,[§] ANDERS MAGNUSSON, M.D.,[‡] LEIF WIDE, M.D.,[§]
and ERIK WILANDER, M.D.[||]

In a prospective study of 103 patients with carcinoid tumors consecutively referred for medical treatment, the most common sites of the primary tumors were the ileum (73%), bronchi (7%), and jejunum (4%). All patients had local metastases, and 96 (93%) also had liver metastases. The most common initial symptoms were diarrhea (32%), ileus (25%), and flush (23%). The overall frequency of diarrhea was 84% and of flush was 75%. Heart insufficiency caused by cardiac valve disease was seen in 33% of the patients. The carcinoid syndrome, including flush, diarrhea, and elevated urinary 5-hydroxyindole acetic acid (5-HIAA) concentrations, was manifested by 69 patients (67%), 64 of whom (93%) had carcinoid tumors of mid-gut origin. Elevated urinary 5-HIAA was found in 91 patients (88%), of which 89 displayed liver metastases. The plasma concentration of the tachykinin neuropeptide K (NPK) was elevated in 67 patients (66%), 63 of whom had tumors of the mid-gut region. Serum pancreatic polypeptide (PP) and human chorionic gonadotrophin α levels were elevated in 43% and 28% of the patients, respectively, and the highest levels were found in patients with metastatic bronchial carcinoid tumors. Thirty-nine of the 103 patients are now dead; 18 died of tumor progression, whereas 14 patients died of heart failure secondary to a carcinoid tricuspidal valve insufficiency. The estimated median survival from the time of histologic diagnosis was 14 years, and from the time of carcinoid syndrome was 8 years.

From the Department of Internal Medicine, University Hospital, Uppsala,[*] the Department of Clinical Chemistry, Karolinska Hospital, Stockholm,[†] the Department of Diagnostic Radiology,[‡] the Department of Clinical Chemistry,[§] and the Department of Pathology,[||] University Hospital, Uppsala, Sweden

THE CARCINOID TUMOR is a neuroendocrine neoplasm with malignant potential and the most frequent of all endocrine gut tumors. When liver metastases have appeared, the hormone secretion from the tumor cells may induce characteristic symptoms of flush, diarrhea, bronchial obstruction, and failure of the right side of the heart. The mechanisms behind the symptoms are not fully known, but serotonin might be a factor involved in diarrhea[1] and the flush might be induced by kallikrein-bradykinin,[2] or by ta-

Submitted for publication: October 13, 1986.

chykinin[3,4] secretion from the tumor cells. Secretion of prostaglandins[5] and histamine[6] also have been associated with carcinoid tumors. Acromegaly and Cushing's syndrome have been reported in patients with carcinoid tumors,[7–9] possibly caused by ectopic secretion of releasing factors from the tumor.[10]

The current study reports data from 103 patients with carcinoid tumors who were consecutively referred to our unit for evaluation. All patients were thus seen at one clinic, by the same physicians, and evaluated according to the same protocols. Special attention was paid to the localization of the primary tumor, metastases, and circulating tumor markers.

Patients

The study includes 103 patients (57 women and 46 men) with carcinoid tumors, seen at the Endocrine Unit of the Department of Internal Medicine, University Hospital, Uppsala, Sweden, during an 8-year period (January 1978–1986). The criterion for inclusion into the study was histologically and clinically verified metastatic carcinoid tumor. The Endocrine Unit serves as a referral unit for central Sweden, which has around 1 million inhabitants. Fifty-four of the patients (52%) in this series came from this region, and the annual incidence rate of individuals with metastatic carcinoid tumors was thus 0.7 patients/100,000 population. The incidence of the carcinoid syndrome was 0.5 patients/100,000 population/year. The remaining 49 patients were referred from other parts of Sweden, either because of an unusually complicated clinical picture or for evaluation for inclusion in clinical trials of specific medical treatments such as interferon.[11]

Altogether 69 patients had been subjected to operation before referral, and an exploratory laparatomy was done at our hospital in an additional 17 patients. These operations were performed to resect the primary tumor, which was possible in 54 patients with intraabdominal tumors and in five patients with pulmonary carcinoid tumors. If a recent tumor specimen from an operation was not available for histopathologic examination, a needle biopsy was executed from liver metastases. Thus, in all patients, the diagnosis of carcinoid tumor was based on a histopathologic examination. The diagnosis of a carcinoid tumor was established before operation in 40 of the 86 patients who had operation (47%), based on histopathology and/or elevated urinary 5-hydroxyindole acetic acid (5-HIAA) concentrations.

Methods

Routine investigations of blood and urine, including hemoglobin content, leucocyte and platelet counts, liver enzymes, serum creatinine, albumin, electrolytes, and fasting blood glucose were performed. The thyroid function was investigated by serum thyroid-stimulating hormone (TSH), thyroxine, and thyroid binding protein. An intravenous glucose tolerance test[12] was performed in 81 patients. Serum pancreatic polypeptide (PP) was determined in 96 patients, human chorionic gonadotrophin α and β subunits (HCG α and β) was determined in 102 patients.[13,14] Serum calcitonin concentrations were measured in 102 patients and gastrin levels were measured in 96 patients.[15,16] The plasma neuropeptide K (NPK) concentration was determined in 101 patients by a newly established radioimmunoassay.[17] Reference values are given in Table 7. The blood samples were drawn in the morning after an overnight fast, and the concentrations at the first visit to our clinic are reported. However, as the technique for NPK analysis is recent, it was impossible to determine its concentration in plasma from the first visit in 30 patients. In these cases the first evaluated plasma sample is used instead.

The urinary 5-HIAA excretion was determined[18] as an average of two 24-hour samples in all patients. Urinary cortisol was analyzed using a commercial radioimmunoassay (Farmos Group, Stockholm, Sweden) in a 24-hour sample of urine.

Computerized tomography (CT scan) and/or ultrasonography techniques were used in 101 patients for evaluation of metastatic disease to the liver. Two patients were not evaluated by these techniques; however, liver metastases were seen at operation in both patients. Ultrasonically guided needle (diameter 2.1 mm) biopsy from the liver metastases was obtained in 90 patients using a previously described technique.[19] In 42 patients with unknown primary tumor location, an angiography of the celiac and mesenteric arteries was performed. All patients were evaluated by roentgenography of the lungs. When the patients had local symptoms from the skeleton, scintigraphy and roentgenography were carried out. Bone marrow aspiration for evaluation of metastases was performed in only a small number of patients. Echocardiography of the heart to detect valvular involvement was performed in 70 patients.

Tumor tissue specimens (N = 103) were stained with hematoxylin and eosin, and investigated morphologically for homogeneous cell structures and characteristic growth patterns of endocrine tumors. For further identification of the tumor as a neuroendocrine neoplasm, the Grimelius (N = 101),[20] Masson (N = 96),[21] and Sevier–Munger (N = 42)[22] silver staining techniques were used. In addition, a technique with monoclonal antibodies for serotonin was used in specimens from 47 patients.[23]

Statistical Analysis

Nonparametric statistical methods as described by Conover[24] were used throughout the study. The median and interquartile ranges were used as indicators of central tendency and variation, respectively. The Mann-Whitney test was used to test for differences between two independent groups. The estimated median survival was calculated as described by Colton.[25]

TABLE 1. *The Median Age at the Time of Diagnosis and the Sex of 103 Patients with Metastatic Carcinoid Tumors Related to the Localization of the Primary Tumor*

Location	Median Age (range)* (years)	Males/ Females

Total	59.0 (51–66)	46/57

* Variation given as the interquartile range.

Results

The Primary Tumor and Metastases

The median age at diagnosis for all patients was 59 years (interquartile range: 51–66 years). The patients with appendical and bronchial carcinoid tumors (Table 1) were younger at the time of diagnosis than the remainder (median age: 38 and 52 years, respectively). A slight predominance of women was seen in the total group (females/males: 57/46).

In 75 patients (73%) the primary tumor was localized to the ileum (Table 2), whereas four patients had jejunal carcinoid tumors, three had cecal tumors, and two had appendical carcinoid tumors. In nine patients the location of the primary tumor was unknown, but six of them probably had tumors of mid-gut origin because of typical histopathologic examination and a positive silver staining with the Masson technique. Thus, 90 of 103 patients (87%) presumably had a mid-gut carcinoid tumor. Intrathoracal carcinoid tumors were found in eight patients; seven had bronchial tumors and one had a mediastinal (thymic?) tumor. The surgeons believed the excision to be radical in only six of the 86 patients who had operation. Five of these patients had a primary tumor of less than 2 cm in diameter. However, liver metastases developed later in all these patients who were considered surgically cured. In 16 patients (17%) multiple primary tumors in the small intestines were found. Local metastases were verified in all patients, and 96 (93%) also had metastases to the liver (Table 3).

Peripheral metastases to sites other than the liver were seen in 31 patients (30%). Of the eight patients with intrathoracal tumors and liver metastases, five revealed metastases to the skeleton and one had metastases to the pituitary gland.

Symptoms and Delay in Diagnosis

Diarrhea was most frequently the first symptom, prompting 33 patients (32%) to consult a physician (Table 4). The second most common initial symptoms were ileus/subileus (25%) and flush (23%). The median duration of any symptoms before diagnosis was 1 year (interquartile range: 0.5–3 years). The patients with subileus/ileus as the first symptom had the shortest delay before diagnosis, *i.e.*, median 0.6 years (interquartile range: 0–3 years). The median time from the onset of diarrhea until diagnosis was 1.5 years (interquartile range: 1–4 years). The patients with flush had a median delay of 2 years (interquartile range: 1–4 years).

Table 5 illustrates the total number of patients with symptoms of diarrhea, flush, intestinal obstruction, tricuspidal heart failure, and asthma. Altogether 69 patients (67%) had a complete carcinoid syndrome with flush, diarrhea, and elevated urinary 5-HIAA concen-

trations (Table 2 and Table 5). In the patients with mid-gut carcinoid tumors, the syndrome was seen in 64 patients (62%). A total of 70 patients (68%) had symptoms of both flush and diarrhea, and 12 of them also had asthmatic attacks. One of these patients with flush and diarrhea had no liver metastases and normal urinary 5-HIAA excretion. The remainder had both liver metastases and elevated urinary 5-HIAA excretion. Four patients (4%) had only flushing and 14 (14%) had only diarrhea. Asthma, which occurred in 15 patients (15%), was not seen as a sole symptom in any patient. Four patients (4%) with intrathoracic tumors had symptoms of invasive growing neoplasm, but no carcinoid symptoms such as flush or diarrhea, and they also had normal urinary 5-HIAA levels. Four patients (4%) with mid-gut tumors did not have any apparent symptoms, and in these patients the primary tumor was detected during operation for ileus.

Thirty-four patients (33%) with cardiac insufficiency had systolic murmur and signs of abnormal tricuspidal valve function at echocardiography. All these patients, except one patient with unknown tumor localization, had carcinoid tumors of mid-gut origin. Only one patient had valve replacement. Thirty patients had a complete carcinoid syndrome and four had diarrhea but no flush. The median age of these patients at the time of diagnosis was 60 years and the median duration of flush and/or diarrhea was 2 years.

CT Scan and Ultrasound Investigations

Abdominal CT scans were performed in 96 patients (93%) and the ultrasound technique was used in 96 patients (93%). One or both techniques were used in evaluating 101 patients, and metastases to the liver were found in 93 patients (92%). At operation, an additional three patients had small miliary metastases in the liver. Multiple liver metastases were found in 73 patients. The size of the liver metastases varied from miliary lesions undetectable by CT scan to large metastases, with a diameter of 10–12 cm, often with central necrosis. On CT scan the metastases had a low attenuation, whereas by ultrasound the echodensity varied considerably.

Histopathology

All tumors had the characteristic growth patterns of endocrine tumors at histopathologic examination. The mid-gut tumors, except one appendical carcinoid tumor, contained homogeneous cells with insular-like growth patterns. A positive staining using the Grimelius silver staining technique was noted in 101 evaluated specimens (Table 6). A positive reaction was found in 83 (88%) of the 96 tumor specimens evaluated with the Masson staining technique. Six of nine tumors of unknown origin had the characteristic growth pattern of mid-gut carcinoid tumors and positive staining using the Grimelius and the Masson techniques. These tumors were therefore presumably of mid-gut type. Negative staining with the Masson technique was found in all bronchial tumors, the mediastinal, the rectal, and three tumors of unknown localization outside the mid-gut. One appendical carcinoid tumor with uncharacteristic growth pattern stained neither with the Masson silver staining technique nor with the specific monoclonal antibodies against serotonin. The rest of the tested mid-gut

tumors had a positive staining with both these techniques.

Tumor Markers

Elevated levels of urinary 5-HIAA were present in 91 patients (88%) (Tables 2 and 7). The median 5-HIAA level was 360 μmol/24 hours (range: 30–3370). Patients with carcinoid tumors located in the mid-gut had a median value similar to that of the whole group, and individuals with bronchial tumors generally had a higher value (median: 480 μmol/24 hours [range: 29–1436]) (Fig. 1). Plasma NPK was elevated in 67 patients (66%) with a median plasma level of 25 pmol/L (range: 7.8–2023). Sixty-three of them (94%) had tumors of the mid-gut type, whereas patients with carcinoid tumors of thoracal origin or of other unusual localizations (Table 2) had plasma NPK median levels close to the normal range (Fig. 2).

The serum PP level was elevated in 43% of the patients, median 0.4 ng/mL (range: 0.03–155). HCG α was above the reference range in 28%; median for men and premenopausal women was 1.5 μg/L (range: 0.34–390), and median for postmenopausal women was 6.15 μg/L (range: 0.41–1500). The highest levels of PP and HCG α were found in patients with bronchial carcinoid tumors (Figs. 3 and 4). A slightly elevated serum gastrin level was observed in 14 patients (15%), and HCG β and calcitonin levels were elevated in 12 and four patients, respectively (Table 7).

TABLE 7. *Tumor Secretory Products ("Markers") in Patients with Carcinoid Tumors*

"Tumor marker"	N	%	Median Value (mean)	Normal Range

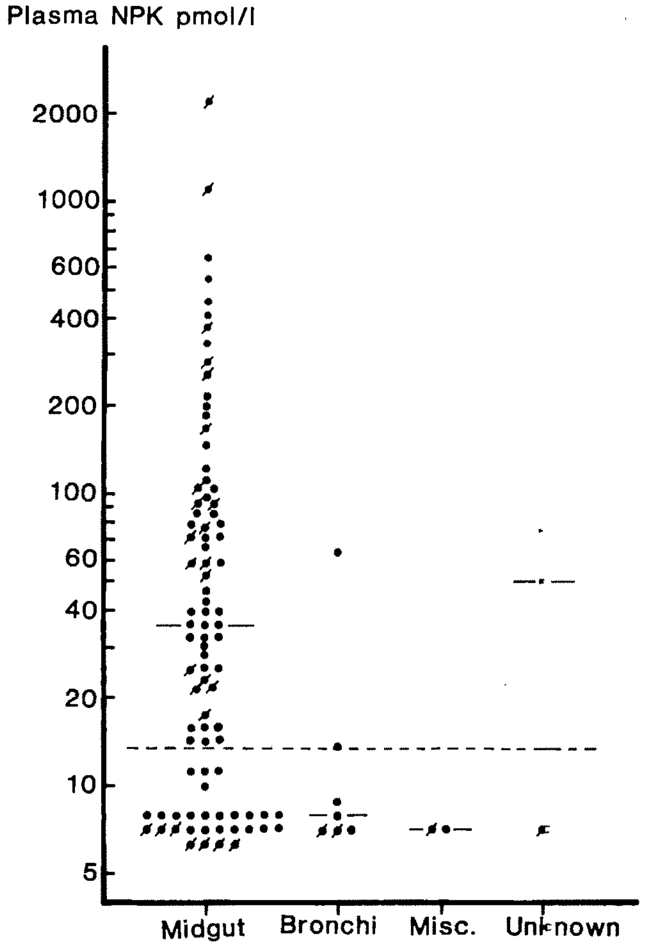

FIG. 2. The concentrations of NPK in plasma from carcinoid patients related to the localization of the primary tumor. Reference level for NPK < 12 pmol/L. NPK concentrations not taken at first visit are marked.

found (Table 8). Only three of 103 patients (3% had no measurable tumor marker in blood or urine, and no patients had metastases to the liver.

The patients with diarrhea had somewhat higher median values for 5-HIAA and NPK than the whole group of carcinoid patients (Table 8, Figs. 5 and 6). The patients with flush had significantly ($p < 0.05$) higher levels of 5-HIAA excretion and plasma concentration of NPK than the whole group. The highest levels of 5-HIAA and NPK were seen in the group of patients who had failure of the right side of the heart and tricuspidal valve insufficiency. The median value for 5-HIAA was 885 μmol/24 hours and for NPK was 75 pmol/L. These levels were significantly higher ($p < 0.01$) than in the whole group of patients.

Clinical and Laboratory Screening

At the first referral to the hospital, 28 patients (27%) had advanced disease with a median weight loss of 10 kg (interquartile range: 7–17 kg) together with a palpable liver-edge more than 5 cm below the right costal margin. Of these patients, 17 are now dead. Nineteen patients (18%) had anemia (B-hemoglobin < 110 g/L). Thirty-six patients (35%) had a sedimentation rate above 20 mm/h, and 15 (14.5%) had leukopenia ($<4.0 \times 10^9$/L). Platelet counts of less than 150×10^9/L were found in 10 patients (9%) (Table 9). Elevated serum levels of the enzymes, ASAT, ALAT, lactate dehydrogenase, as well as serum alkaline phosphates and bilirubin were present in 22 patients. Thirteen patients (12%) showed abnormality in three of the four liver function tests, and all these patients had a liver enlarged by more than 5 cm below the right costal margin. Eleven of these patients are now dead. Twenty-seven of 45 patients with palpable liver had one or more abnormal liver function tests. Serum albumin level below 34 g/L was found in 38 patients (37%). All patients had normal serum levels of sodium, potassium, and chloride.

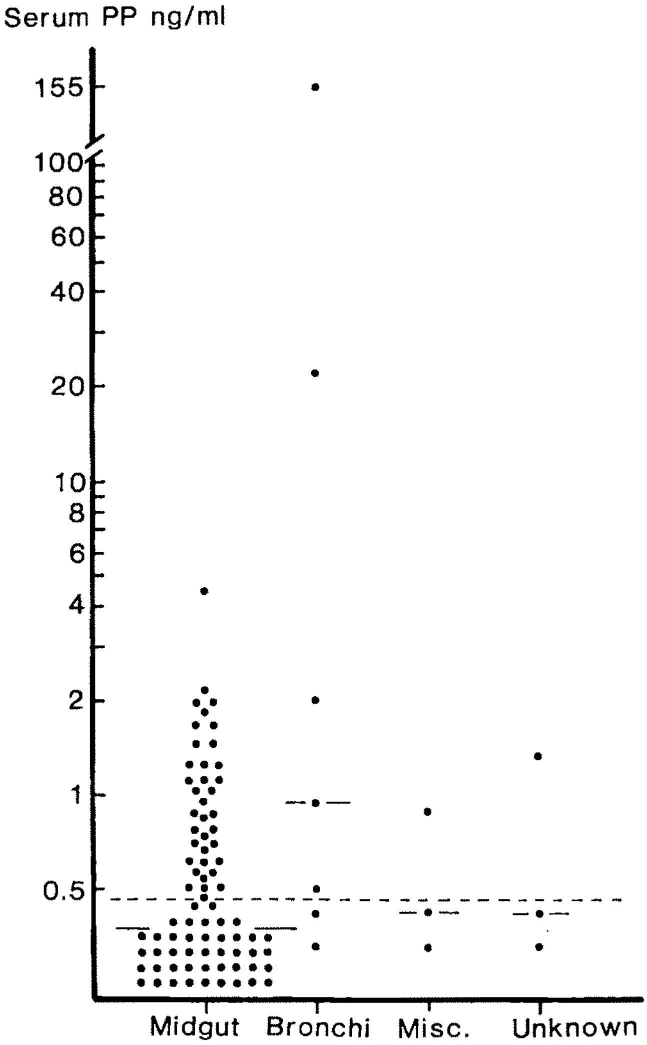

FIG. 3. The concentrations of pancreatic polypeptide (PP) in serum from patients with carcinoid tumors, related to the localization of the primary tumor. Reference level for PP < 0.4 ng/mL.

Additional Endocrine Diseases

Five patients had been treated earlier for hyperthyroidism, and a nodular goiter was found in four patients. Four patients had insulin-dependent diabetes mellitus. Endocrine screening revealed three patients with hypothyroidism and one with a primary hyperparathyroidism, verified by surgery. One patient with a bronchial carcinoid tumor had Cushing's syndrome developed probably as a result of ectopic corticotropin releasing factor (CRF) production in the tumor.

Accessory Tumor Diseases

An accessory malignant tumor was seen in five patients (5%). Two patients had mammary carcinoma. Chronic myelogenic leukemia, rectal, and prostatic carcinoma were seen in three patients. The accessory tumor disease was diagnosed after the carcinoid tumor in three of the patients.

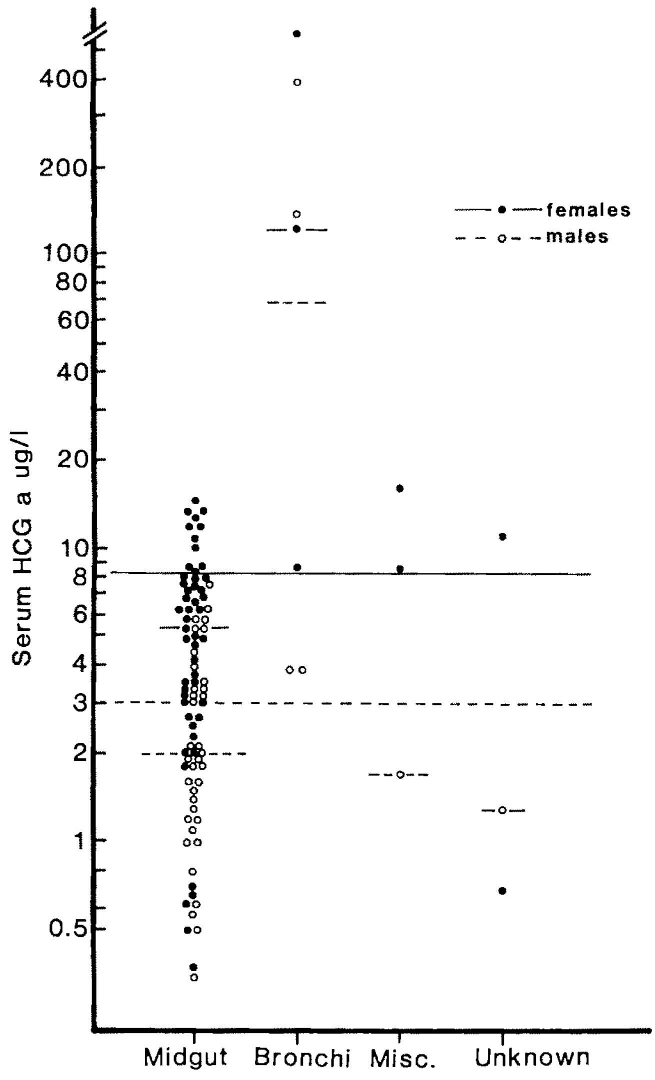

FIG. 4. The concentrations of HCG α in serum from patients with carcinoid tumors, related to localization of the primary tumor localization. Reference level for HCG α men and premenopausal women < 3.0 μg/L; postmenopausal women < 8.5 μg/l.

TABLE 8. *The Median Concentrations of 5-HIAA and NPK in Relation to the Clinical Symptoms in the Patients*

Signs	N	5-HIAA (μmol/24 hours)*	NPK (pmol/L)*
Diarrhea	86	425 (178–1038)	35 (11–91)

Survival

The median time from histologically diagnosed carcinoid tumor until referral to our unit for evaluation, the doctor's delay, was 0.5 years (interquartile range: 0.2–3.2 years).

Altogether 39 of 103 patients (38%) died during the observation period. Tumor progression was the cause of death in 18 patients (46%), whereas in 14 patients (36%) cardiac insufficiency was the main reason (Table 10). All

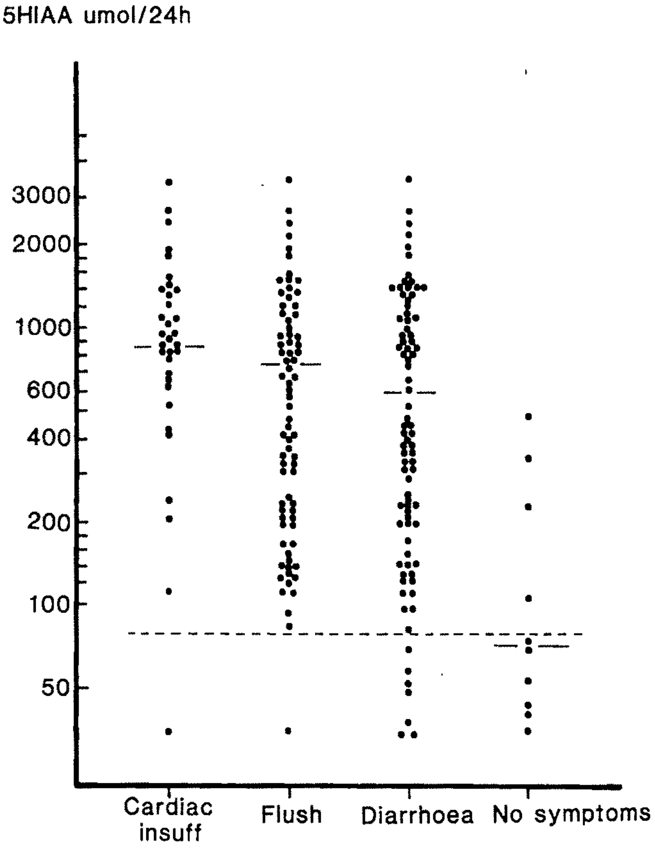

FIG. 5. The concentrations of urinary 5-HIAA excretion related to the symptoms in patients with carcinoid tumors.

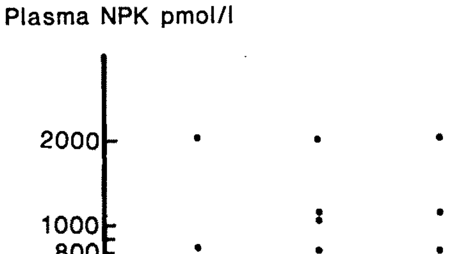

FIG. 6. The concentrations of NPK related to the patient's symptoms.

these patients also had an advanced tumor disease. The median time from carcinoid symptoms until death in these 39 deceased patients was 3.5 years, and the median time from histologic diagnosis was 2 years For the whole patient group, the estimated 5-year survival rate from the time of histologic diagnosis was 65% and from the time of definitive symptoms of a carcinoid syndrome, flush, or diarrhea was 67% (Figs. 7 and 8). Estimated median survival from the time of histologic diagnosis was 14 years, and from the time of carcinoid syndrome was 8 years. The survival curves are not adjusted for the age of the patients.

Discussion

Carcinoid tumors, originally described by Oberndorfer[26] in 1907, have proved to be a heterogeneous group of tumors. However, Williams and Sandler,[27] in 1963, proposed that carcinoids arising in three areas: the fore-gut (bronchi, stomach, duodenum), mid-gut (jejunum, ileum, appendix, and proximal colon) and hind-gut (distal colon and rectum), form three distinct groups based on histologic, biochemical, and clinical evidence. The relevance of this subdivision in the clinical situation, however, has to be further evaluated. The expression of clinical symptoms as well as the hormone production may vary among patients with different categories of carcinoid tumors. Furthermore, there are considerable differences in clinical symptoms, hormone production, and tendency to become malignant even in tumors within the same group, *e.g.*, the appendical carcinoid tumor, which is the most frequent carcinoid tumor, rarely becomes malignant or induces clinical symptoms caused by hormone production, whereas ileal carcinoid tumors often give rise to metastases and the carcinoid syndrome.[28] Thus, carcinoid tumors, which are the most frequent neuroendocrine tumors, deserve careful assessment and discerning management.

In the current prospective study of a large number of patients with carcinoid tumors, we have concentrated on hormone production related to localization of the carcinoid tumors and metastases. All patients, who were consecutively referred to our unit during an 8-year period, were investigated according to the same procedure.

In agreement with other studies that were done retrospectively, the majority of our patients with metastatic carcinoid tumors had mid-gut tumors.[28,29] As the patients were referred for treatment of clinical symptoms, *e.g.*, carcinoid syndrome, it is not surprising that most of the tumors were of mid-gut origin, since mid-gut carcinoid tumors most often display hormone-related clinical symptoms.

The annual incidence rate of metastatic carcinoid tumors in our study was 0.7 patients/100,000 population, and the annual incidence of the carcinoid syndrome was 0.5/100,000. This is less than found in the necropsy study by Berge and Linell[30] who demonstrated an annual incidence of malignant carcinoid tumors of 2.1 patients/100,000 population. The true annual incidence of clinically significant tumors is likely to be somewhere between the results of these two studies. Our clinical study may underestimate the true frequency because patients with only local metastases are treated surgically and thus not referred and very old individuals with metastatic tumors are rarely referred to our clinic. The average age of 59 years at the time of diagnosis is in agreement with other studies.[28,31] The lower onset ages of appendical and pulmonary carcinoid tumors is also in accordance with earlier studies.[31]

Our data emphasize the difficulty in determining the surgical curability at the time of the primary operation. Even in patients with small primary tumors (diameter < 2 cm) that are considered to be radically removed, metastatic carcinoid disease may later develop. However, appendical carcinoid tumors, which are often small (less than 2 cm) and frequently incidentally found at operation for appendicitis, seldom develop metastases. Only two of our patients with metastatic carcinoid disease had the primary tumor located to the appendix. This may support the suggestion that appendical carcinoid tumors originate from neuronal cells instead of the enterochromaffin cells,[32,33] which are the source of other mid-gut carcinoid tumors. The majority (93%) of our patients had liver metastases, but unusual localizations of metastases, such as the skeleton, the ovary, and the pituitary, were also found. These unusual localizations frequently occurred in patients with tumors of fore-gut origin.

The most frequent initial symptom was diarrhea (32%), followed by symptoms of intestinal obstruction (25%) and flushing (23%). The relative predominance of diarrhea and flushing in our material may be due to the high frequency of patients with the carcinoid syndrome (67%). The delay between initial symptom and diagnosis was shortest in patients with symptoms of intestinal obstruction (0.6 years), but considerably prolonged when the disease presented with flush and/or diarrhea (1.5–2 years).

The frequency of cardiac involvement was in the same range as found by Graham-Smith, who found cardiac involvement in 41% of patients with carcinoid syndrome.[34] All but one of our patients with tricuspidal valve disease had a primary tumor of mid-gut origin.

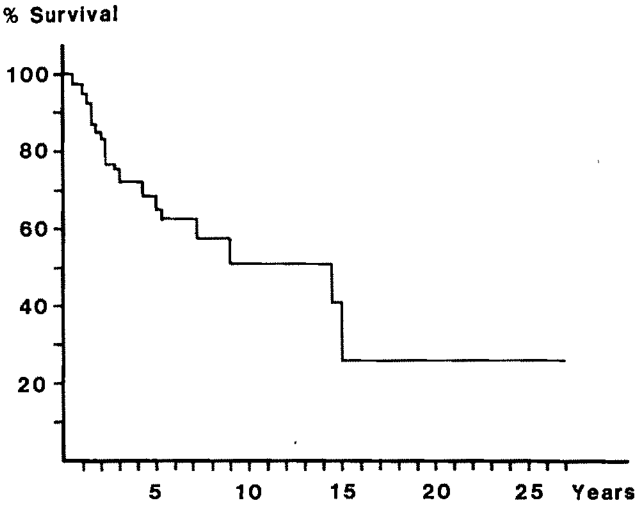

FIG. 7. Survival from the time of histologic diagnosis in patients with carcinoid tumors. The estimated 5-year survival rate was 65%.

The mean age at diagnosis of a carcinoid tumor and cardiac failure did not diverge from that of the rest of the patients, but the median duration of symptoms before referral and start of treatment was 2 years, which is somewhat longer than for other patients. The patients in whom carcinoid cardiac involvement developed presumably have hormonally active tumors, secreting a spectrum of biologically active substances, and the levels of urinary 5-HIAA and plasma NPK were significantly higher in this group than in all patients (Figs. 5 and 6). None of our patients with bronchial carcinoid tumors displayed cardiac valve disease, although these patients had high excretion of 5-HIAA in the urine. However, plasma NPK was not significantly increased in patients with bronchial carcinoid tumors and liver metastases (Fig. 2). Serotonin has been proposed earlier to be an etiologic factor for the development of carcinoid heart disease, including fibrosis of the cardiac valves. How-

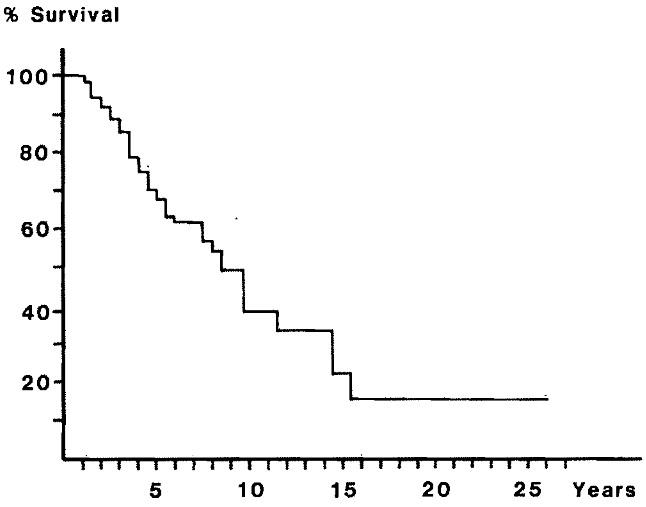

FIG. 8. Survival from the time of definite symptoms in patients with carcinoid syndrome. The estimated 5-year survival rate was 67%.

ever, tachykinins, such as neurokinin A and substance P, have recently been demonstrated to stimulate fibroblast growth,[35] and the same tachykinins are known to be secreted in a majority of our patients with mid-gut tumors. Thus, tachykinin-like substances might be etiologic agents for the fibrosis seen in the carcinoid heart disease.

There was a difference in tumor-secreted products between patients with mid-gut and fore-gut carcinoid tumors as stated previously. High levels of urinary 5-HIAA were seen in both groups, but NPK was predominantly recorded in patients with mid-gut tumors. HCG α and PP were found in high levels in patients with bronchial carcinoid tumors, whereas these peptides were only slightly elevated in the mid-gut group. This is in accordance with the theory of Williams and Sandler,[27] which proposed different origin and biochemistry of bronchial and ileal carcinoid tumors.

Flushing was seen in 77 patients; all but one patient had elevated urinary 5-HIAA, whereas 60 patients had elevated plasma NPK. Both serotonin and tachykinins are vasoactive substances that may be responsible for the carcinoid flush. However, the serotonin receptor antagonist (Ketanserin®) can eradicate the diarrhea but not the flush,[36] which indicates that serotonin cannot be the only mediator of flush. Furthermore, the somatostatin analogue SMS 201-995 (Sandoz Pharmaceuticals Corporation, Stockholm, Sweden) can block the carcinoid flush, and in parallel, reduce the plasma NPK levels, indicating a role of tachykinins in the etiology of flush (unpublished data). Similarly, plasma NPK is known to increase during spontaneous and pentagastrin stimulated flush.[4] In patients with malignant carcinoid tumor, urinary 5-HIAA and plasma NPK were the best "markers," especially in tumors of mid-gut origin.

Plasma concentrations of PP and HCG α have been reported earlier to be frequently elevated in patients with malignant carcinoid tumors.[37,38] However, in this more extended study, the frequency is somewhat lower, which might be explained by the fact that in the current study we have only reported the concentrations at the time of referral to the unit. However, the concentrations frequently increased with time. Another explanation might be that initially only advanced cases were referred, whereas more recently, many patients with less advanced disease have been sent to us.

Eighty-six patients had diarrhea, and of these patients, 79 had elevated urinary 5-HIAA and 61 had elevated plasma NPK. The diarrhea may possibly depend on the intestinal effects of serotonin secreted from the tumor,[36] but some patients may also display short-bowel syndrome after resection of intestinal carcinoid tumors. Local mechanical effects on the gut by the tumor itself cannot be ruled out as some patients had normal circulating serotonin levels and normal urinary 5-HIAA excretion.

Seven patients had no detectable metastases in the liver. However, two patients had elevated 5-HIAA excretion in the urine and symptoms of both flush and diarrhea, and one patient had elevated 5-HIAA excretion and no symptoms. In addition, one patient had elevated serum HCG α and diarrhea. Only three patients revealed no tumor markers to be followed and none of them had liver metastases. The lack of relation between symptoms, urinary 5-HIAA excretion, and liver metastases might depend on the detection limits of the CT scan and ultrasound techniques, which are unable to perceive lesions less than 0.5 cm in diameter. However, occasionally patients with carcinoid tumors of mid-gut origin may have the carcinoid syndrome in the absence of hepatic metastases.[39]

Most patients had normal results of routine laboratory tests. Elevated levels of liver enzymes, particularly alkaline phosphatases, occurred, especially in patients with large metastases in the liver, and among our patients, 11 of 13 with elevated levels of liver enzymes and enlarged liver are now dead. Thus, these findings together with loss of weight seem to be a poor prognostic factor.

An accessory malignant neoplasm was found in only five patients, which is a lower frequency than published in other reports: Barclay and Shapira reported a frequency of 17%[40] and Dawes et al. reported a frequency of 15%.[41] The Mayo Clinic study[28] had a second malignancy in 5% of patients, which is comparable with our findings. The differential diagnosis between carcinoid tumor, mammary cancer, and small cell lung cancer may be difficult in some instances, and the exact diagnosis frequently depends on the experience of the pathologist.

The prognosis of the patients with carcinoid tumors varies depending on the localization of the primary tumor and the stage of disease. In patients with only local metastases, Dawes et al.[41] found that 80% of the patients lived for 5 years. When liver metastases were present, the 5-year survival rate was 19–38%.[28,42,43] Our findings of an estimated 5-year survival rate of 65% in our patients with malignant carcinoid tumors seems interesting. Although different patient materials might not be compared, our data might indicate that new therapeutic alternatives such as interferon, which was used in 92 of the patients,[11] and new somatostatin analogues (SMS 201-995), which were used in about 15 patients, might add years to life and not only improve the quality of life. Besides earlier awareness and diagnosis of the disease, this might contribute to the better survival data.

In conclusion, the current prospective study of malignant carcinoid tumors demonstrates that mid-gut tumors, except appendical tumors, often become malignant, and that diarrhea and flushing are the most frequent clinical symptoms when liver metastases have appeared. Furthermore, cardiac insufficiency is often seen, especially in patients with mid-gut carcinoid tumors and carcinoid syndrome. Nearly all patients have one or more tumor-secreted products, which can be used as markers for both diagnosis and follow-up. Urinary 5-HIAA excretion is elevated in carcinoid tumors irrespective of the origin of the primary tumor, whereas levels of NPK is elevated mainly in patients with mid-gut carcinoid tumors. Fore-gut tumors, on the other hand, more often present high levels of HCG α and PP. The most frequent causes of death were tumor progression followed by carcinoid heart failure. Our survival data are somewhat more favorable than those earlier reported, which may indicate development of more effective therapeutic alternatives such as interferon and somatostatin analogues.

Use of Tubes and Radiographs in the Management of Small Bowel Obstruction

ROBERT E. BROLIN, M.D., F.A.C.S., MARK J. KRASNA, M.D., and BRUCE A. MAST, B.A.

From the UMDNJ–Robert Wood Johnson Medical School, New Brunswick, New Jersey

During the past 10 years 311 consecutive patients were admitted with 342 episodes of small bowel obstruction (SBO). There were 193 cases of partial small bowel obstruction (PSBO) and 149 cases of complete small bowel obstruction (CSBO) as determined by interpretation of the abdominal radiographs done on admission. The purpose of this review was to determine the reliability of the admission plain abdominal radiographs and subsequent upper gastrointestinal (UGI) contrast studies in predicting the need for operative intervention. The use of nasogastric tubes (NGT) *versus* nasointestinal (long) tubes (NIT) was correlated with the following outcome variables; length of hospital stay (LOS), timing of operative intervention, incidence of postoperative complications, and duration of postoperative ileus. Long tubes (NIT) were used in 64 episodes of PSBO and 81 episodes of CSBO, whereas nasogastric tubes (NGT) were used in 116 cases of PSBO and 68 cases of CSBO. Thirty-eight of 193 (19%) patients with PSBO required operation (20 of 116 with NGT and 18 of 64 with NIT), whereas 125 of 149 (84%) patients with CSBO required operation (60 of 68 with NGT and 65 of 81 with NIT). Need for operation was not correlated with whether or not long tubes passed beyond the pylorus; 50 passed *versus* 33 not passed in operative groups ($p = 0.15$). Twelve of 83 patients with NIT had operation within 24 hours *versus* 52 of 80 patients with NGT ($p < 0.001$). In six of 64 patients who had surgery within 24 hours, complications developed *versus* in 39 of 99 patients operated on more than 24 hours after admission ($p \leq 0.001$). In 29 of 83 patients treated with NIT, postoperative complications developed *versus* in 16 of 80 patients with NGT ($p \leq 0.04$). The mean duration of postoperative ileus in patients with NIT was 7 days *versus* 4.1 days for NGT patients ($p < 0.001$). The mean LOS was 12.2 days for NGT patients *versus* 21 days for patients with NIT ($p < 0.001$). Barium UGI contrast studies were performed in 57 patients to establish the presence of obstruction. In 34 of 57 patients the UGI disclosed mechanical obstruction that required operative intervention. In the remaining 23 patients no obstruction was demonstrated, and all 23 patients recovered without operation. In conclusion, there is no inherent superiority of NIT *versus* NGT in the treatment of SBO. Long tubes (NIT) were associated with a significantly greater LOS, duration of postoperative ileus, and incidence of postoperative complications, probably because of the significantly greater delay in operation in patients treated with NIT *versus* NGT. The radiographic distinction between PSBO and CSBO is clinically important in that 84% of patients with features of CSBO required operation *versus* only 19% of patients with PSBO.

THERE IS CONSIDERABLE controversy regarding both the effectiveness of tube decompression and what constitutes "reasonable delay" before operation in mechanical small bowel obstruction. Strangulation of obstructed bowel has been attributed to delayed decisions for operative treatment.[1,2] The incidence of postoperative complications is 5–10 times greater with strangulation than with cases of nonstrangulated obstruction.[1,3,4] It is well known that strangulation of the bowel occurs without specific signs and symptoms. Thus, many surgeons believe that all patients with mechanical intestinal obstruction should have laparotomy as soon as fluid losses have been replenished.[4–6] On the other hand, the diagnosis of "partial" bowel obstruction is based on clinical and radiographic signs that, in the opinion of most surgeons, warrants a trial of tube decompression rather than immediate operative intervention.[7,8] There are still others who believe that a trial of nonoperative tube decompression should be rendered to any patient with obstruction who does not have obvious signs of strangulation.[9–11] These diverse opinions can be attributed to the paucity of objective criteria that can reliably distinguish cases of obstruction that are likely to respond to tube

decompression from those that require early operation. It was the purpose of this review to determine the reliability of the admission clinical signs and plain abdominal radiographs in predicting the need for operative intervention in mechanical small bowel obstruction. We also compared the effectiveness of nasogastric (NGT) with nasointestinal or long tubes (NIT) in terms of successful avoidance of operative treatment.

Clinical Material

For the 10-year period beginning January 1, 1976 through December 31, 1985, 311 consecutive patients with 342 episodes of mechanical small bowel obstruction were admitted to Robert Wood Johnson University Hospital. This review excluded patients with adynamic ileus, fecal impaction (including meconium ileus), and mesenteric vascular occlusion. Plain abdominal radiographs were taken at the time of admission in all but six patients with incarcerated hernia in whom the clinical diagnosis of complete mechanical intestinal obstruction was confirmed at operation. There were 193 cases of partial bowel obstruction and 149 cases of complete obstruction. The distinction between partial and complete mechanical obstruction was based on the radiologist's interpretation of the admission abdominal radiographs. The primary distinguishing radiographic feature between partial and complete obstruction is the presence of gas in the colon above the peritoneal reflection. Cases of complete obstruction were characterized by dilated loops of small bowel with fluid levels and no visible gas in the colon, whereas cases of partial obstruction showed clear-cut evidence of colonic gas in addition to dilated loops of small bowel (Fig. 1).

The frequency of the presenting clinical symptoms is shown in Table 1. Nausea, vomiting, and abdominal pain were reported in 99% of the 342 episodes of obstruction. Abdominal pain was typically colicky in nature. Patients who denied either pain or vomiting had plain abdominal radiographs that showed dilated small bowel loops with fluid levels. Sixty-one per cent of patients in whom the duration of obstipation was documented denied passage of stool or flatus for more than 24 hours. Seven patients had obvious peritonitis, six of whom had hypotension and a temperature ≥ 100 F at the time of admission. Other admission criteria that were assessed included the presence of abdominal tenderness and leukocyte count. Neither of these correlated with the need for operation. Table 2 shows the etiology of obstruction. Adhesions from previous abdominal operations was the most common cause of obstruction, accounting for 59% of cases of complete obstruction and 73% of cases of partial obstruction. Intra-abdominal malignancy was the second most common case of obstruction, accounting for 17% of cases of complete obstruction and 10% of cases of partial obstruction. Hernia and Crohn's disease were the third and fourth most frequent causes, respectively. The correct admission diagnosis of small bowel obstruction, partial or complete, was made in 322 cases (94%). The admission diagnoses for the remaining 20 cases are shown in Table 3.

NIT were used in 64 cases of partial obstruction and 81 cases of complete obstruction, whereas NGT were used in 116 cases of partial obstruction and 68 cases of complete obstruction. Generally, the attending surgeon decided whether a long or short tube would be used, although occasionally the surgical house staff made this decision. The suspected etiology of obstruction did not

TABLE 1. *Presenting Clinical Features*

Features	No. of Cases (%)
Nausea/vomiting	340 (99)
Abdominal pain	339 (99)
Obstipation ≥24 hours	102* (61)*
Peritonitis	7 (2)
Fever ≥100 F	7 (2)
Hypotension ≤90 mmHg systolic	6 (2)

* The duration of obstipation was clearly documented in 102 cases of which 61% had obstipation ≥ 24 hours.

TABLE 2. *Etiology of Obstruction*

	PSBO	CSBO
Adhesions	140	88
Malignancy	18	25
Hernia	—	22
Crohn's	12	2
Other*	23	12

* Other causes of obstruction included gallstone ileus (4), volvulus (4), intussusception (4), abdominal abscess (4), bezoar (2), diverticulitis (2), and cause undetermined (10). Twelve cases of early postoperative obstruction were included in the adhesion group.

TABLE 3. *Incorrect Admission Diagnoses and Outcome**

	Radiographic Diagnosis	
Admission diagnosis	PSBO	CSBO
Abdominal pain	10 (7)	—
Pancreatitis	3 (2)	1 (1)
Pelvic inflammatory disease	3 (1)	—
Acute cholecystitis	2 (0)	—
Pneumonia	1 (0)	—

* Abdominal pain of uncertain etiology was the most frequent "incorrect" diagnosis. Numbers in parentheses are the number of patients who required operation, 11 of 20 (55%) in all. The admission radiographs were consistent with partial obstruction in 19 of these 20 patients.

TABLE 4. *NGT* Versus *NIT and Outcome**

	NGT	NIT	
Need for operation	80/184	83/145	
Operation ≤24 hours	52/80	12/83	($p < 0.001$)†
Postoperative complications	16/80	29/83	($p \leq 0.04$)†
Duration of postoperative ileus (days)	4.1	7.0	($p < 0.001$)†
Length of hospitalization (days)	12.2	21.0	($p < 0.001$)†

* The type of tube used for decompression did not impact on need for operative intervention. However, a significantly greater number of patients managed with NGT compared with NIT had operation within the first 24 hours of hospitalization. The incidence of postoperative ileus and length of hospitalization were significantly greater in patients managed with long tubes.

† Statistics computed by Fisher's exact test.

influence the selection of one type of tube over the other. The type of tube used also did not influence requirement for operative intervention. Thirty-eight of 193 (19%) cases of partial obstruction required operation, including 20 of 116 (10%) treated with nasogastric tubes and 18 of 64 (28%) treated with long tubes. One hundred twenty-five of 149 cases (84%) of complete obstruction required operation, including 60 of 68 (89%) treated with nasogastric tubes and 65 of 81 (80%) treated with long tubes. Tube decompression was not used in the 13 remaining cases. Long tubes passed through the pylorus in 50 of the 83 cases (60%) that required operation compared with 49 of the 64 cases (76%) treated with long tubes that did not require operative intervention ($p = 0.15$ by chi-square test). The use of nasogastric tubes *versus* long tubes was correlated with the following outcome variables: need for operation, timing of operative intervention, number of postoperative complications, duration of postoperative ileus, and length of hospitalization. These data are shown in Table 4.

One hundred eighteen of 191 patients (62%) who were managed for at least 24 hours by tube decompression showed signs of clinical or radiographic improvement within the first 24 hours of treatment. Only eight patients (5%) whose obstructions ultimately resolved without operation did not show signs of improvement during the first 48 hours of tube decompression. Improvement was recognized radiographically as decrease gaseous distention of the small bowel and clinically b spontaneous passage of stool and/or flatus. Thirty-eigh of these 191 patients (20%) did not respond to tub decompression and eventually had operation.

TABLE 5. *Timing of Operation* Versus *Postoperative Complications**

Complication	<24 Hours (N = 64)	>24 Hours (N = 99)
Wound infection	1	13
Pneumonia	1	6
Fistula/abscess	—	6
Myocardial infarction	—	1
Pulmonary embolus	—	1
Death	4	12
Total	6	39

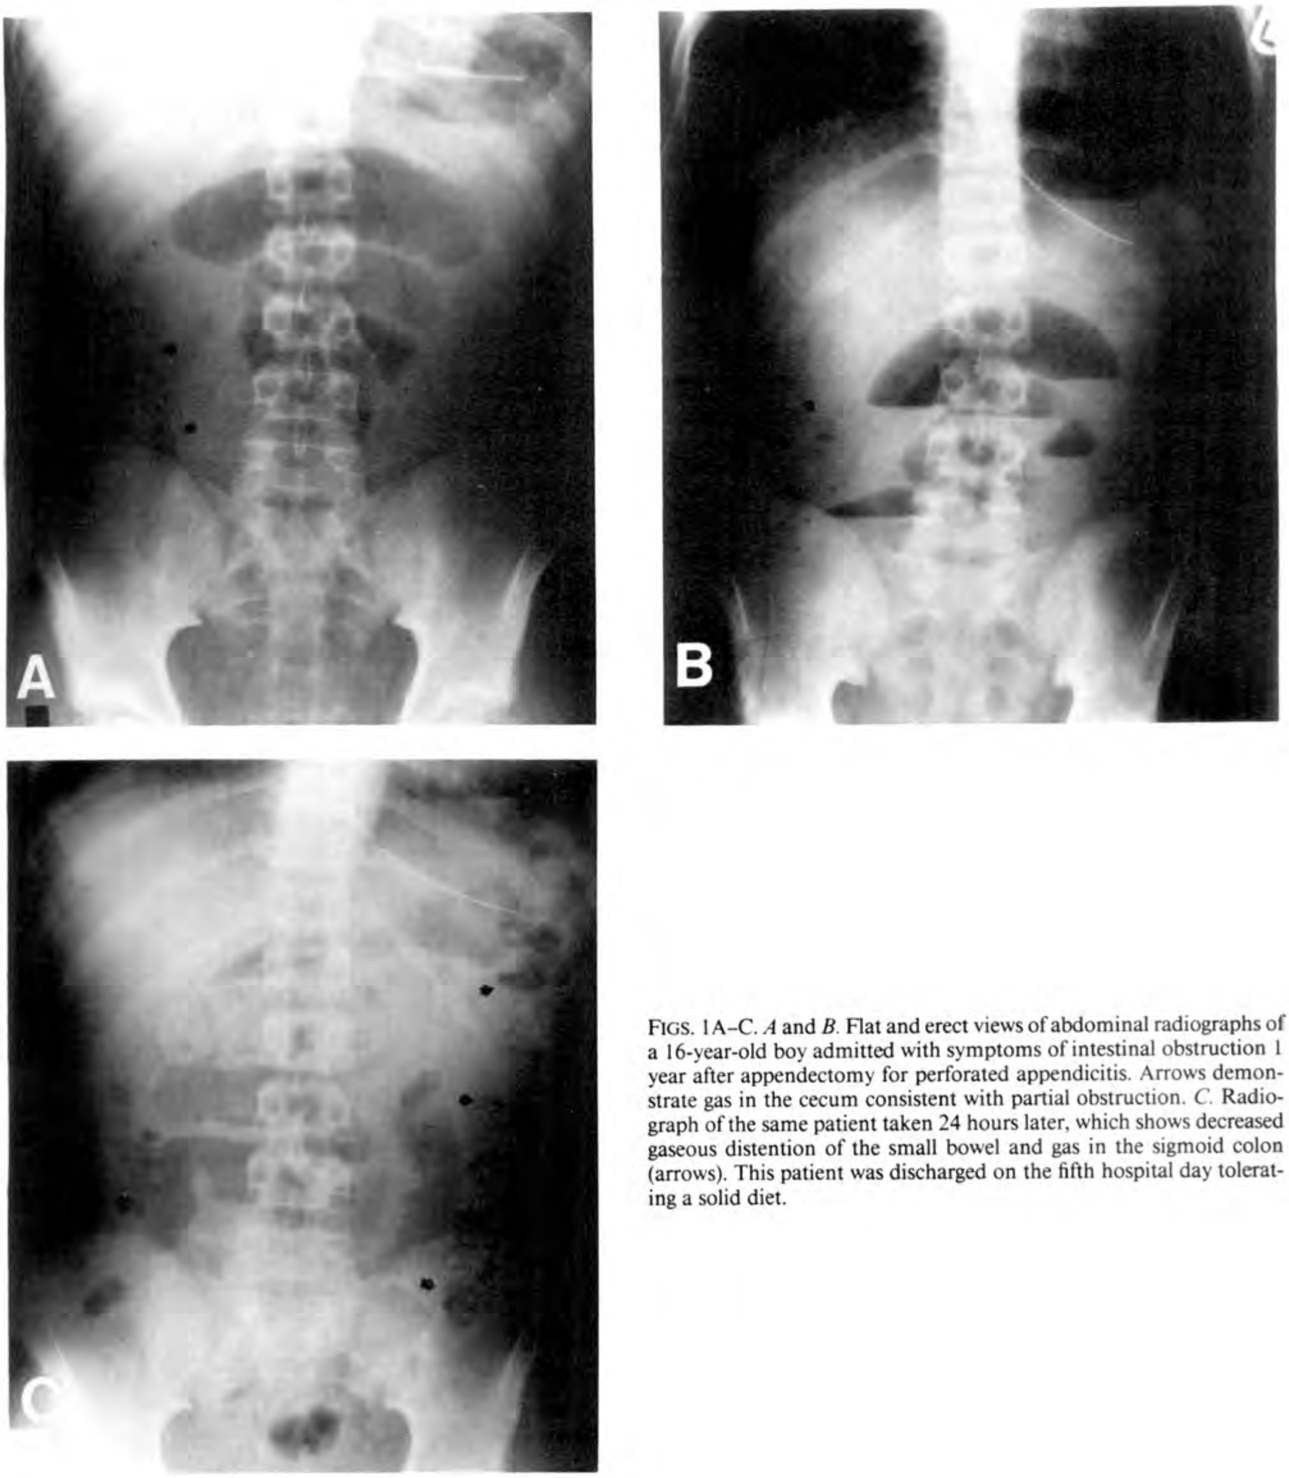
* Infectious complications were significantly more common in patients operated on more than 24 hours after admission. Fistulae and abscesses occurred in patients with either strangulation or iatrogenic perforation of the bowel.

Table 5 shows the correlation between timing of operative intervention and the frequency of postoperativ complications. Of the 64 patients who had operatio within 24 hours of admission, postoperative complications developed in six patients (9%) compared with in 3 of 99 patients (39%) who had operation more than 2 hours after admission ($p \leq 0.001$ by chi-square test Twenty-four of the 311 patients died (7.7%). Twenty-si patients had strangulation obstruction at operation Nine of these 26 patients had operation within 24 hour of admission with three subsequent deaths compare with six deaths among the 17 patients who had operation more than 24 hours after admission. Eight patient other than those with strangulation died after operation Seven of these patients had advanced carcinomatosi and one died of a massive stroke. The remaining seven patients who died did not have operation. Three of these patients were moribund with septic shock at the time o admission and four had inoperable abdominal malignancies.

Barium upper gastrointestinal (UGI) contrast studie were performed in 57 patients to establish the presence of mechanical obstruction. In 34 of the 57 patients the contrast study disclosed mechanical obstruction, and each of these patients required operative intervention In the remaining 23 patients no obstruction was demonstrated and all of these patients recovered without having operation. Those patients who required operation demonstrated either a discrete point of blockage (Fig 2B) or failure of the barium to reach the cecum after 18–24 hours (Fig. 3). In the 23 patients who did no require operation all or nearly all of the barium had entered the cecum within the 24-hour observation period.

Discussion

There is surprisingly little information in the surgical literature regarding the reliability of either clinical o radiographic criteria in predicting the need for operativ intervention in patients with intestinal obstruction Table 6 shows data from six reports on small bowe obstruction published during the past 30 years. The reports of Wolfson et al. and Hofstetter were restricted t patients with adhesive obstruction, whereas the remainder included all well-documented cases of me



FIGS. 1A–C. *A* and *B*. Flat and erect views of abdominal radiographs of a 16-year-old boy admitted with symptoms of intestinal obstruction 1 year after appendectomy for perforated appendicitis. Arrows demonstrate gas in the cecum consistent with partial obstruction. *C*. Radiograph of the same patient taken 24 hours later, which shows decreased gaseous distention of the small bowel and gas in the sigmoid colon (arrows). This patient was discharged on the fifth hospital day tolerating a solid diet.

chanical small bowel obstruction.[2,4,8,10–12] Becker, Hofstetter, Wolfson et al., and Stewardson et al. distinguished partial from complete obstruction, although Stewardson et al. excluded cases of partial obstruction from their review. Of note are the variable percentages of patients who required operation *versus* those who responded to tube decompression and avoided operative treatment. Becker and Silen et al. strongly advocated early operation for all cases of small bowel obstruction citing the abuse of tube decompression as a primary cause of death. On the other hand, Stewardson et al., Bizer et al., and Wolfson et al. recommend trials of

TABLE 6. *Small Bowel Obstruction: Previous Clinical Reports**

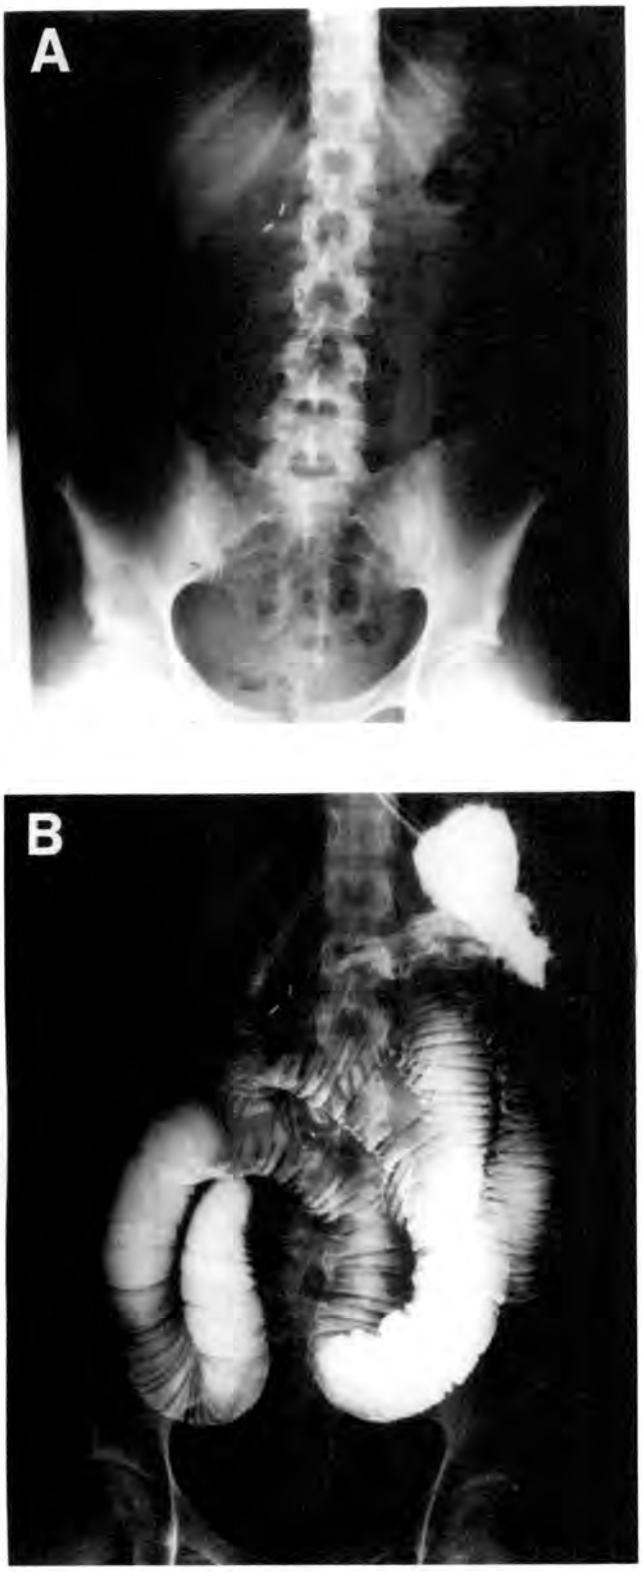
	Total Patients	No. of Patients Operated On (%)	% with Strangulation	% Total Mortality
Becker[2]	412	297 (72)	22%	12%
Silen et al.[4]	480	316 (66)	23%	11%
Stewardson et al.[10]	238	112 (47)	11%	5.5%
Hofstetter[11]	52	31 (60)	8%	1.9%
Bizer et al.[8]	405	267 (66)	10%	6.7%
Wolfson et al.[12]	127	48 (38)	12%	1.5%
Brolin (current series)	311	163 (53)	9%	7.7%

* The percentage of patients with mechanical small bowel obstruction who had operation ranged from a low of 38% (Wolfson et al.) to a high of 72% (Becker). The two series with the lowest mortality (Hofstetter, Wolfson et al.) included only patients with adhesive obstruction.

nonoperative tube decompression for all patients who lack the typical signs of intestinal strangulation. Hofstetter stated that the duration of nonoperative tube decompression should not exceed 24 hours. The overall incidence of operative intervention appears to have decreased during the past 2 decades. Table 6 also shows the incidence of strangulation and overall mortality in these clinical reports. The chronology of these reports shows a decreased incidence of both strangulation and mortality despite more conservative recommendations in treatment. In the current series the incidence of strangulation and mortality was 9% and 7.7%, respectively. These data suggest that factors other than early operative intervention are responsible for the decreased incidence of strangulation and mortality during the past 30 years.

The primary radiographic criterion for diagnosis of partial small bowel obstruction is gas in the colon above the peritoneal reflection.[6,13] The presence of colonic gas above the peritoneal reflection suggests that some air has passed beyond the obstruction, hence the blockage is incomplete. Because gas can be introduced into the rectum by digital examination, air in the rectum alone is not sufficient for making the diagnosis of partial obstruction. The radiographic diagnosis of "partial" bowel obstruction probably encompasses a number of cases of early complete obstruction, which may also show gas in the colon on the admission abdominal radiographs. In these early cases, the colonic gas antedates the time of obstruction and has not yet been evacuated. The typical radiographic features of mechanical intestinal obstruction may be absent in cases of high jejunal obstruction. Figure 2 shows the plain abdominal radiograph and subsequent barium UGI contrast study of a patient with complete obstruction 60 cm below the ligament of Treitz. The plain x-rays showed a paucity of gas in the small and large bowel without air fluid levels on the erect view. Plain radiographs performed 18 hours later showed one visible loop of small bowel. The barium UGI was performed to rule out obstruction of the proximal small bowel. In this series, barium UGI contrast studies were extremely reliable in determining need for operation. All patients whose barium studies demonstrated either a discrete site of blockage or failure of barium to reach the cecum within a 24-hour observation period ultimately required operation. Patients who recovered with tube decompression had contrast studies that showed complete transit of barium and no evidence of obstruction. Despite their great accuracy, the use of barium UGI studies should probably be limited to cases in which the diagnosis of mechanical obstruction is in doubt. Patients admitted to the hospital with partial obstruction who have not responded to tube decompression after 48 hours should be operated on without a UGI contrast study. On the other hand, patients responding to tube decompression who have no past history of abdominal surgery should have a predischarge UGI examination to rule out malignancy as a possible cause of obstruction. Barium UGI studies are probably most useful in distinguishing cases of early postoperative obstruction from prolonged adynamic ileus.

In this report, the selection of a nasogastric or long tube was made arbitrarily at the time of admission. Although some surgeons have strong sentiments for use of one type of tube over the other, there are no data demonstrating superiority of long *versus* short tubes in the treatment of mechanical intestinal obstruction. Wolfson and associates recently touted the efficacy of long tube decompression in the treatment of adhesive obstruction.[12] They made these claims despite the fact that approximately two thirds of their patients with complete obstruction did not respond to tube decompression and required operation. They also stated that passage of a long tube beyond the pylorus was of "significant predictive value" with respect to avoiding operative treatment, although no statistical support for those claims was provided. In the current review there was no correlation between need for operative intervention and whether or not long tubes passed beyond the pylorus. Fifty of the 83 patients (60%) managed with long tubes who required operation had passage of their tube into the upper small



FIGS. 2A and B. *A*. The erect admission radiograph of a 26-year-old woman who had symptoms of small bowel obstruction 2 years after laparotomy for blunt trauma. There is little gas in either the small or large bowel. *B*. A barium contrast study performed 24 hours later, which showed a discrete point of obstruction in the right midabdomen. Several hours later this patient had laparotomy and lysis of a single adhesive band.

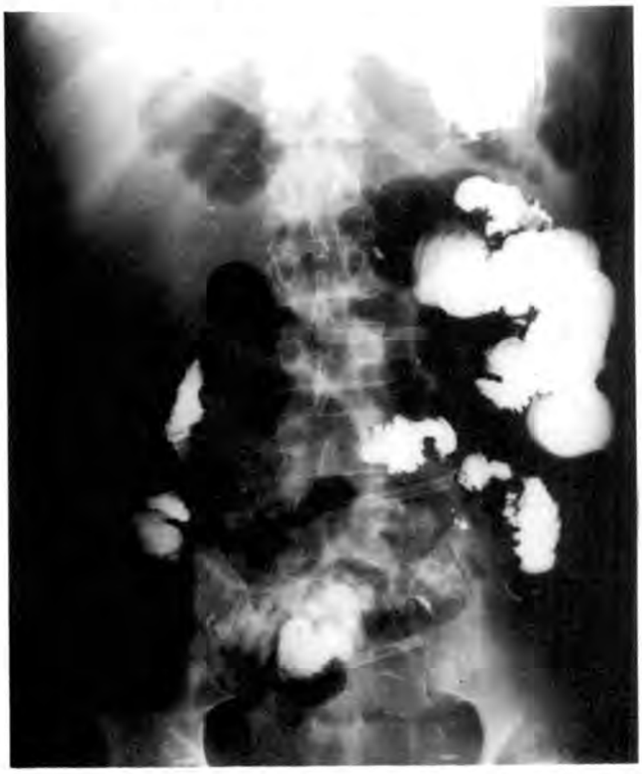


FIG. 3. Twenty-four hour delayed film of barium UGI performed on a 42-year-old man in whom signs of obstruction developed 6 days after right hemicolectomy and ileostomy for perforated cecal volvulus. The contrast study was performed after 4 days of nasointestinal tube (NIT) decompression. (Tube was removed during study). Although some barium emptied through the ileostomy, much remained in the upper small bowel. This patient had lysis of multiple adhesions on the eleventh postoperative day and had a subsequently uneventful recovery.

bowel. There was also no difference between nasogastric and nasointestinal tubes with respect to avoiding operative intervention. In this review there were several negative features associated with the use of long tubes compared with nasogastric tubes. Long tubes were associated with a significantly greater number of postoperative complications and significantly longer duration of both postoperative ileus and hospitalization (Table 3). These negative findings were most likely due to the significantly greater delay in operative intervention in patients managed with long tubes compared with nasogastric tubes. All of these data clearly show that the mere passage of a long tube into the upper small bowel does not justify delay in operative intervention.

Surgeons who favor a nonoperative trial of tube decompression for all cases of obstruction except those with signs of strangulation base support for their position on the substantial percentage of cases that resolve with tube decompression alone. Wolfson and associates operated on only 38% of 127 patients with adhesive obstruction after an empirical trial of tube decompression.[12] The incidence of postoperative complications was 30% in their report, including a 4.8% operative mortality rate and a 12% incidence of strangulation. These results are comparable to those reported by surgeons who favor early operative intervention.[4,9,10] It seems obvious that a rigid attitude favoring either an empirical trial of tube decompression on one hand or immediate operative intervention on the other will do disservice to a substantial number of patients with small bowel obstruction. It was the primary purpose of this review to determine the reliability of admission clinical and radiographic criteria in predicting the need for operative treatment. The actual decision for operative intervention was based on the clinical judgement of the attending surgeon. At our institution there is no consensus of opinion among surgeons regarding the appropriate timing of operation for small bowel obstruction. Hence, the radiographic diagnosis of partial bowel obstruction did not always result in a nonoperative trial of tube decompression and, by the same token, a number of patients with complete obstruction had prolonged treatment by tube decompression. Nonetheless, in accordance with the axiom that all cases of partial obstruction will resolve with tube decompression and all cases of complete obstruction will require operation, the admission abdominal radiographs predicted the clinical course in 82% of cases in this series. Duration of obstipation was less reliable in predicting need for operation as 31% of patients with obstipation $\leq$ 24 hours required operation, whereas 38% with obstipation for more than 24 hours were successfully treated by tube decompression. On the basis of these data we recommend that all patients with radiographic features of complete obstruction have operation as soon as fluid losses have been replaced, whereas patients with features of partial obstruction and no clinical signs of strangulation be given a trial of tube decompression with the reasonable likelihood of avoiding operation. Although 16% of patients with complete obstruction successfully avoided operation, we could not identify specific features that distinguished those patients from the 84% who required operation.

There are several causes of obstruction that generally warrant an empirical trial of tube decompression. These include Crohn's enteritis, advanced abdominal carcinomatosis, and early postoperative obstruction. Obstruction due to Crohn's disease usually resolves after 24–48 hours of treatment with parenteral steroids and antibiotics. This treatment regimen was successful in avoiding operation in 11 of the 14 cases of obstruction caused by Crohn's enteritis in this report. Patients with obstruction secondary to abdominal tumor metastasis represent a treatment dilemma because of their generally debilitated condition on one hand and the low probability of response to tube decompression on the other. Furthermore, operative treatment is frequently difficult because of blockage by tumors at multiple sites along the bowel. In this series the hospital mortality rate of obstruction due to metastatic disease was 64%. Intestinal obstruction in the early postoperative period frequently resolves with tube decompression.[14–16] With early postoperative obstruction, many surgeons prefer a long tube to a nasogastric tube because of the theoretical advantage of internal enterolysis as it passes distally through the bowel. In the early postoperative period mechanical obstruction must be distinguished from prolonged ileus. Patients who do not improve after 48 hours of tube decompression should have a barium UGI contrast study. In this review, barium contrast studies were highly reliable in determining need for operative intervention. The relatively high mortality associated with early postoperative obstruction has been attributed to unnecessary delay before re-exploration in two previous reports.[14,15] Patients who have had multiple hospital admissions and operations for adhesive obstruction probably present the greatest dilemma in terms of appropriate timing of operative intervention. At the outset, these patients are usually treated by tube decompression with the hope of avoiding another operation. During this 10-year review there were 25 such patients admitted an average of 2.64 times per patient with a mean interval of 1.8 months between admissions. All but four of these patients ultimately required operation, and none of the surviving patients have been readmitted with obstruction during the subsequent follow-up period. We therefore recommend that patients who have had more than two hospital admissions for obstruction during a 6-month interval have laparotomy.

That delayed operative intervention in this review was associated with a significantly greater number of postoperative complications supports the frequently quoted adage, "The sun should never be allowed to set (or rise) on a case of mechanical intestinal obstruction." Those who espouse this philosophy cite that there is no reliable method of distinguishing simple from strangulated obstruction.[4,6,9,17] In this review there was no correlation between the timing of operation and mortality from strangulation obstruction. However, complications other than strangulation were significantly more common among patients operated on more than 24 hours after admission (Table 4). These complications occurred almost exclusively in patients whose admission radiographs showed complete as opposed to partial obstruction. The only postoperative complications that occurred in patients admitted with partial obstruction were three wound infections and one anastomotic leak after bowel resection for strangulation. The wound infections occurred in elderly patients who were operated on at a mean 7.3 days after admission. These data suggest that increased complications other than strangulation represent the most cogent mitigating factor favoring early operation for complete small bowel obstruction.

An incorrect admitting diagnosis was made in only 20 of the 342 cases (6%) in this series (Table 3). Inaccurate diagnosis delayed operation more than 24 hours in all of the misdiagnosed patients who required operative intervention. One patient with radiographic features of complete obstruction had strangulation after a misdiagnosis of acute pancreatitis. There were also two cases of strangulated volvulus that were misdiagnosed as partial obstruction. Progression of radiographic signs led to operation within 24-36 hours in both cases, and both patients survived. These misdiagnosed volvulus cases were the only cases of strangulation in the 193 episodes of "partial" small bowel obstruction.

In summary, the requirement for operative intervention is the most critical decision to be made during the initial evaluation of patients with intestinal obstruction. In this review the radiographic distinction between partial and complete obstruction was the most reliable determinant of need for operative treatment in that 84% of patients with complete obstruction required operation compared with only 19% of patients with partial obstruction. Operations delayed more than 24 hours after admission were associated with a significantly greater number of complications. Ninety-one per cent of the postoperative complications occurred in patients with complete obstruction. On the basis of these data, we recommend that all patients with features of complete obstruction have operation shortly after admission, whereas patients with partial obstruction be given a trial of tube decompression with the likelihood of avoiding operative treatment. Nearly 75% of patients initially managed by tube decompression who ultimately avoided operation showed clinical or radiographic signs of improvement during the first 24 hours, whereas only 5% of patients whose obstructions resolved without operation did not show improvement within the first 48 hours of treatment. We therefore recommend that trials of nonoperative tube decompression for partial obstruction not exceed 48 hours. Clinical deterioration or increased small bowel distention on abdominal radiographs during the course of tube decompression warrants prompt operative intervention.

A Prospective, Randomized Trial of Abdominal Wound Drainage in Gastric Bypass Surgery

DAVID SHAFFER, M.D., PETER N. BENOTTI, M.D., ALBERT BOTHE, JR., M.D., ROGER L. JENKINS, M.D.,
and GEORGE L. BLACKBURN, M.D., PH.D.

A prospective, randomized trial was conducted in 194 morbidly obese patients who had gastric bypass to determine the effect of subcutaneous closed suction drainage on wound infection rates. There was no difference in the incidence of postoperative wound infection with the use of drains compared with simple abdominal closure. Organisms isolated from infected wounds were predominantly skin flora and did not differ between the two groups. Patients with wound infections had significantly prolonged hospitalizations compared with those without infections, but in the subgroup with wound infections there was no difference in hospitalization time between the drainage or control groups.

*From the Department of Surgery, Harvard Medical School,
and the New England Deaconess Hospital,
Boston, Massachusetts*

OBESE PATIENTS who have abdominal surgery are at increased risk for development of postoperative wound infections.[1,2] Both prolonged operating time and the development of hematomas, seromas, or dead space in the subcutaneous tissue are believed to predispose to wound infection.[1,3] The theoretical advantage of wound drainage, with removal of blood and serum and the obliteration of dead space, would thus seem to make the routine use of subcutaneous drains in abdominal closure in the obese patient particularly attractive. Several retrospective, nonrandomized reports in both the general surgical[4,5] and gynecologic[6,7] literature support this contention. However, few controlled, randomized trials specifically address the question of abdominal wound drainage in clean or clean-contaminated cases.

We report the results of a prospective, randomized trial of prophylactic closed suction drainage of the subcutaneous tissue in 194 patients who had gastric bypass.

Materials and Methods

All patients who had gastric bypass at our institution between June 1982 and August 1986, were included in the study. All patients received identical pre- and postoperative care according to a written protocol. Patients were admitted 1 or 2 days before surgery. They received a hexachlorophene abdominal scrub 3 times per day before surgery and a hexachlorophene shower and shampoo the evening before surgery. Patients not allergic to penicillin received cefazolin, 1 g intravenously, before and after operation before June 1983, after which the dose of cefazolin was doubled.[8] Patients allergic to penicillin received either vancomycin with an aminoglycoside (2 patients) or an aminoglycoside alone (4 patients). Three patients with valvular heart disease received appropriate endocarditis prophylaxis.[9] Subcutaneous heparin, 5000 units every 8 or 12 hours depending on antithrombin III level, was begun before operation and continued until discharge.[10]

In the operating room the abdomen was prepared with chlorhexidine detergent followed by povidone-iodine solution. After the skin incision, the subcutaneous tissue was separated to the fascia by lateral traction of the wound edges to minimize bleeding and tissue necrosis.[11] The fascia was divided with electrocautery. All patients had gastric bypass as previously described[12] with retrocolic Roux-en-Y gastrojejunostomy with a 10–15 mL gastric pouch created with a double row of staples and side-to-side jejunojejunostomy made using the stapler. The gastrojejunal anastomosis was performed in two layers with nonabsorbable sutures. The

Submitted for publication: February 2, 1987.

abdomen was irrigated with normal saline and the fascia closed in a single layer with interrupted, heavy nonabsorbable monofilament or synthetic absorbable suture.

Patients were then randomized into two groups. After irrigating the subcutaneous tissue with 25% povidone-iodine solution, one group had their abdominal wounds closed over a closed suction drain brought out through a separate stab incision. Wounds in the control group were closed without drains. The skin was closed with skin staples.

Drains were left to self-suction and removed when drainage was less than 30 mL/24 hours. Drains were not irrigated. Patients were discharged from the hospital when able to take one liter of fluids by mouth in a 24-hour period. Skin staples were removed approximately 2 weeks after operation at the first outpatient visit. All wounds were examined by both a surgeon and nurse practitioner with a minimum follow-up of 1 month.

Wounds were defined as infected if pus was present at the incision site. Serous drainage with negative bacterial cultures and without clinical evidence of infection were not considered wound infections. Suture sinuses were also not included in the infected group. All operations were classified as clean-contaminated.[1]

Preoperative per cent ideal body weight was calculated by dividing the preoperative weight by the mean ideal body weight for height according to Metropolitan Life Insurance Company tables (1955). Duration of operation was measured from skin incision to closure.

Results were compared using the chi-square test or Student's t test where appropriate.

Results

One hundred ninety-four morbidly obese patients had gastric bypass between June 1982 and August 1986. All patients were entered into the study. One hundred two patients were randomized to receive closed suction drains in their abdominal closure. Wounds were closed without drains in the remaining 92 patients. Thirty-day follow-up of wounds was available for all patients.

The two groups are compared in Tables 1 and 2. Risk factors previously associated with postoperative wound infection, including age, weight, preoperative hospital stay, duration of operation, additional procedures performed, diabetes mellitus, and chronic steroid use, were similar between the drainage and control groups.

There were 11 wound infections in the drainage group (10.8%) compared with 10 in the control group (10.9%). The overall rate of postoperative wound infection was 10.8% (Table 3). In addition, three patients (2 drainage, 1 control) had secondary wound infections develop after re-exploration for complications (1 anastomotic leak, 2 acute gastric dilatations). Subcutaneous drains were used in two of these three reoperations. Because these wound infections occurred after contaminated cases, they are excluded from further analysis.

There has been a decrease in the wound infection rate over the 5-year study period, from 20% in 1982 to 7.4% in 1986 (Fig. 1), although this difference is not statistically significant.

Wound cultures were available in 16 of 21 patients (8 drainage, 8 control). There was no significant difference in either the number or type of organism isolated between the two groups (Table 4). *Staphylococcus* sp. and *Streptococcus* sp. were the most common organisms isolated (76%). Six patients (2 drainage, 4 control) had more than one organism isolated. Five patients with wound infections had concomitant cholecystectomy performed at the time of gastric bypass (3 drainage, 2 control). Intraoperative bile cultures were available in

three of these patients and were negative. A wound infection developed in the only patient to have incidental appendectomy and cholecystectomy. *Escherchia coli* was isolated from the appendix (bile cultures were negative), whereas wound drainage grew *Staphylococcus aureus* and *Bacteroides fragilis.*

In both the drainage and control groups, patients in whom postoperative wound infections developed had significantly longer hospital stays compared with patients without complications. The mean postoperative stay for infected *versus* noninfected patients was 17.2 ± 13.7 *versus* 8.2 ± 1.8 days ($p < 0.001$) and 12.1 ± 8.4 *versus* 8.6 ± 1.7 days ($p < 0.01$) in the drainage and control groups, respectively. Of those patients with wound infections in the two groups, there was no significant difference in either the severity of infection or the duration of postoperative stay.

Discussion

We conducted a prospective, randomized trial of closed suction drainage of abdominal wounds in 194 patients who had gastric bypass over a 5-year period at a single institution. There was no significant difference in the incidence of postoperative wound infection with the use of subcutaneous drains compared with simple abdominal closure.

Streptococcus sp.	—	2	2 (10%)
Enterobacter	2	—	2 (10%)
Bacteroides fragilis	—	1	1 (5%)
Diptheroids	1	1	2 (10%)

* More than one organism may have been isolated from a single wound infection.

The overall rate of postoperative wound infection in our study is comparable to other published reports for clean-contaminated cases[1,2] and gastric bypass procedures.[5,13–18] In a study comparing closed suction drainage with heavy nylon stay sutures to reduce wound dead space in morbidly obese patients, Kozol et al.[13] similarly found no reduction in wound infections with the use of closed suction drains.

Although both groups were comparable with respect to known risk factors for postoperative wound sepsis, the drainage group had a slightly higher number of patients with prolonged preoperative hospital stays. Of 14 patients in the drainage group hospitalized 3 or more days before surgery, wound infections developed in three patients (preoperative hospitalizations of 6, 10, and 13 days, respectively) compared with none of six patients in the control group. However, even excluding these patients, the use of subcutaneous drains did not significantly reduce the incidence of wound infections.

Several factors may account for the lack of efficacy of drains in this study. The use of subcutaneous drains in obese patients is based on the assumption that the large subcutaneous layer results in increased dead space and the accumulation of blood and serum, which in turn predispose to wound infections. However, techniques aimed at reducing the amount of bleeding and tissue trauma and necrosis, such as separating the subcutaneous fat by lateral traction and the use of electrocautery, may reduce the volume of tissue fluid accumulation and diminish the effect of drains.

Secondly, by providing a route for bacteria to get into the wound as well as out, drains may increase the risk of infection.[19–21] Although the risk is certainly less for closed suction drains than simple conduit (Penrose) drains,[22] the high percentage of skin contaminants isolated suggest that retrograde infection may still play a role.

Closed suction drains may also become obstructed with tissue fragments and fail to function properly. Although we did not routinely irrigate the drains or document patency at the time of removal, the total volume of drainage or the day of drain removal was not appreciably different between infected and noninfected wounds.

Also noteworthy is a reduction in the rate of wound infections during the course of this trial. Two factors may account for this. A preliminary review of our data revealed that increasing the perioperative dose of cefazolin in 1983 from 1 to 2 g resulted in a significant reduction in wound infections.[23] Secondly, the institution of more rigorous wound surveillance as a byproduct of this study, which has been shown by others[24,25] to lead to a reduction in wound infection rates, may have also contributed to this trend.

Gastrointestinal Anastomoses

Factors Affecting Early Complications

R. KENT JEX, M.D., JON A. VAN HEERDEN, M.B., BRUCE G. WOLFF, M.D.,
ROGER L. READY, R.N., and DUANE M. ILSTRUP, M.S.

From the Section of Gastroenterologic and General Surgery, the Section of Colon and Rectal Surgery, and the Section of Medical Research Statistics, Mayo Clinic and Mayo Foundation, Rochester, Minnesota

A retrospective review of gastric and colonic anastomoses during a recent 12-month period was performed at the Mayo Clinic. One hundred sixty-nine patients had gastroduodenal or gastrojejunal anastomoses (Group I). Five hundred nineteen patients had ileocolonic or ileorectal (222) and colocolonic or colorectal (297) anastomoses (Group II). Major anastomotic complication rates for Group I patients were: leaks, 1%; hemorrhage, 2%; and stenosis or obstruction, 2%. Reoperations and deaths secondary to anastomotic complications during the postoperative period were 2% and 0.6%, respectively. Corresponding rates for Group II were 2%, 1%, and 4%, with reoperative and anastomotic death rates of 1% and 0.2%, respectively. In Group I patients, length of operation had a significant effect ($p < 0.01$) on anastomotic complications. In Group II patients, a significant increase in complications was related to the presence of obstruction ($p < 0.001$), recent weight loss (>10 pounds) ($p < 0.02$), malignancy ($p < 0.04$), and sepsis ($p < 0.05$).

THE REPORTED RATES of major complications involving anastomoses of the gastrointestinal tract have varied widely, and debate has centered around the causes of these complications in regard to anastomotic leaks, in particular. To determine the rates of major complications and to determine the pre- and intraoperative factors that affect these rates we reviewed our experience with gastrointestinal anastomoses during a recent 12-month period.

Materials and Methods

Between January 1, 1982 and December 31, 1982, 688 patients had abdominal surgery at the Mayo Clinic with performance of an anastomosis involving either the stomach (gastroduodenal, gastrojejunal) or the colon (ileocolonic, ileorectal, colocolonic, or colorectal). The records of these patients were reviewed retrospectively for multiple preoperative (Table 1) and intraoperative (Table 2) variables that might affect the rate of anastomotic complications. A "major complication" was defined as leak, hemorrhage, or obstruction (stenosis). Leaks were defined by any evidence of internal or external fistula, abscess, or intra-abdominal sepsis, and they were identified either at reoperation or *via* examinations with contrast medium. Hemorrhage was defined as significant bleeding (>100 mL/h) in the immediate postoperative period that required emergency reoperation or hemodynamic resuscitation. Minor anastomotic bleeding that did not require transfusion was not included. Obstruction or stenosis was defined as narrowing, kinking, or swelling of significant magnitude to delay or halt normal passage of intestinal contents. This obstruction was defined either endoscopically or radiographically with contrast material. Gastric atony was not included in this group. The rates of minor complications (*e.g.*, wound infection, urinary tract infection, and pneumonia), reoperations, and operative mortality were also analyzed. Results were analyzed by using Fisher's exact test (two tailed), the Wilcoxon test, or Student's t-test where appropriate.

Results

Group I

One hundred sixty-nine patients (88 men and 81 women; mean age: 60 years) had either gastroduodenal or gastrojejunal anastomosis. The rates of major anastomotic complications are listed in Table 3. There were no significant differences in these rates among the various

Submitted for publication: February 2, 1987.

types of gastric anastomoses, with overall rates for leaks of 1%; hemorrhage, 2%; and stenosis/obstruction, 2%. Reoperations were required in six patients within 3 months of the initial procedure; however, only three patients had re-exploration because of anastomotic complications (2%). The operative mortality rate was 9% overall, with one death (0.6%) secondary to anastomotic complication. Tables 1 and 2 show the rates of anastomotic complications and the various preoperative and intraoperative factors. None of the preoperative factors were significant predictors of complications; however, the presence of malignancy and recent or intraoperative radiation therapy approached significance ($p = 0.07$; $p = 0.09$, respectively). No significant differences were noted when comparing age or sex of patients with or without complications.

Length of surgery was the only intraoperative variable that was significant: 247 minutes for those with anastomotic complications compared with 174 minutes for those without complications ($p < 0.02$). Patients with malignancy had an 8% rate of major complication compared with 1% for patients without malignancy ($p = 0.07$).

Group II

Five hundred nineteen patients (264 men and 255 women; mean age: 63 years) had anastomosis involving the colon or rectum (ileocolonic, ileorectal, colocolonic, colorectal). The rates of major complications were leaks, 2%; hemorrhage, 1%; and stenosis/obstruction, 4%. The reoperation rate was 2% overall (1% secondary to anastomotic complications) and the mortality rate was 3% (0.2% secondary to anastomotic complications).

There were no statistically significant differences in the rates of leak (1% and 5%) or hemorrhage (1% and 0%) for anastomoses performed above or below the peritoneal reflection. However, there was a significant difference in the rates of stenosis/obstruction for intraperitoneal and extraperitoneal anastomoses (3% and 9%, $p < 0.02$). Minor complications were noted with increased frequency ($p < 0.0001$) in anastomoses involving the ileum, whereas an increased rate of reoperations ($p = 0.02$) was noted in colocolonic or colorectal anastomoses. No differences were noted when comparing age or sex of patients with or without anastomotic complications.

Several preoperative variables were associated with an increased risk of anastomotic complication (Table 1). Obstruction of the colon (37% and 3%, $p < 0.0001$), recent weight loss of greater than 10 pounds (malnutri-

Discussion

Much discussion has appeared in the literature concerning anastomotic complications, primarily anastomotic leaks after colorectal surgery. Rates as high as 50% have been reported when routine postoperative visualization with contrast material has been performed, with corresponding clinical leak rates of 10–30% reported after low anterior resections.[1] Leak rates have been lower for intraperitoneal colonic and gastric anastomoses (8% and 5%, respectively).[2,3] In this study, leak rates were 1% for gastric and 2% for colonic anastomoses. For colonic anastomoses, there was an increased rate of anastomotic leak in patients with colorectal anastomoses (5% compared with 1%), but this was not statistically significant.

Several studies have reported various factors to be related to an increased rate of anastomotic complications: advanced age, diabetes mellitus, weight loss, emergency surgery, infection, hypotension, prolonged surgery, inexperienced surgeon, and performance of extraperitoneal anastomosis.[4–6] Our review identified preoperative bowel obstruction as the strongest predictor of anastomotic complications (37% compared with 3%, $p < 0.0001$) in colonic surgery; other predictors were significant weight loss ($p < 0.02$), presence of malignancy ($p < 0.04$), and sepsis ($p < 0.05$). No factors in gastric surgery except length of operation ($p = 0.02$) were significant.

The reports concerning the technical aspects of anastomoses have yielded conflicting data concerning anastomotic complications when comparisons were made between sewn and stapled anastomoses,[7–11] single- and double-layered sewn anastomoses,[12] and everted and inverted sewn anastomoses.[13] However, the consensus of these studies is that inverted anastomoses are superior to everted anastomoses and that no significant differences exist between single or double and sewn or stapled anastomoses, although the rate of stenosis is increased with stapled or double-layered anastomoses compared with single-layered anastomoses. In our study, the majority of anastomoses were constructed in a double layer, inverting fashion and there was no statistically significant difference when comparing stapled and sewn anastomoses. We did, however, note an increased rate of obstruction/stenosis in anastomoses performed to the rectum ($p = 0.02$).

Our study highlights that the level of anastomotic complications, particularly leaks, can be held to an acceptable level with attention to technical details regardless of whether the anastomosis is constructed with the stapler or hand-sewn, performed by a resident or a staff surgeon, or performed above or below the peritoneal reflection. The technical principles involving all anastomoses warrant repetition: (1) good blood supply, (2) no tension, (3) adequate lumen, (4) water-tight anastomosis, and (5) no distal obstruction. There is no significant effect of diabetes mellitus, steroid use, age, or sex on rates of complications, but radiation therapy and hypotension may play a role. Colonic obstruction, malignancy, weight loss/malnutrition, and sepsis all had a significant role in anastomotic complications in patients who had colonic anastomoses, and particular care should be taken when these factors are present.

A Scientific Evaluation of Operative Choledochoscopy in Acute Cholangitis

WAN-YEE LAU, F.R.C.S., F.R.A.C.S., KIN-KEE CHONG, F.R.C.S., SHEUNG-TAT FAN, F.R.C.S., KIN-WAH CHU, F.R.C.S., WAI-CHUN YIP, F.R.C.S., GAH-PANG POON, F.R A.C.S., and KWOK-KEE WONG, F.R.A.C.S.

A prospective study to determine the safety and effectiveness of choledochoscopy in acute cholangitis and acute suppurative cholangitis due to common bile duct stones was conducted on 70 patients. Common bile duct pressures determined on the first 20 patients showed that choledochoscopy was unlikely to cause cholangiovenous reflux. Laboratory and clinical parameters revealed that choledochoscopy did not cause septicemia, worsen cholangitis, or provoke acute pancreatitis. There was no iatrogenic injury during choledochoscopy, and the choledochoscopic views were minimally affected by cholangitis. Choledochoscopy detected overlooked stones after conventional methods of exploration of common bile ducts in 14.3% of patients and it helped to remove impacted stones in 2.9% of patients. As a result, the incidence of retained stones after choledochoscopy was 1.4%. Time spent in choledochoscopy was short, and the total postoperative septic complication rate was only 10%. There was no operative mortality. It is concluded that choledochoscopy is safe and effective in cholangitis.

From the Government Surgical Unit, Queen Mary Hospital, Hong Kong

OPERATIVE CHOLEDOCHOSCOPY in elective common bile duct surgery is widely accepted because of its value and safety.[1–14] By direct inspection through the choledochoscope, the risk of retained common bile duct stones is reduced and latent pathologic lesions and anatomic abnormalities are discovered. Furthermore, through the operative channel, biopsy of mucosal lesions and removal of impacted stones can be performed.[14,15]

The place of choledochoscopy in acute cholangitis is less well defined as biliary tract infection makes the procedure potentially more dangerous. Continuous irrigation under pressure is required in choledochoscopy to maintain distension of the ductal system and to clear bile and debris to allow good vision. Cholangiovenous reflux of infected bile occurs if the common bile duct pressure is high, resulting in bacteremia, endotoxemia, and septicemia.[16,17] Similarly, reflux of infected bile under pressure up the biliary system may worsen cholangitis, and reflux into the pancreatic duct may cause acute pancreatitis.[2,18] Leakage of irrigant around the choledochoscopes is inevitable and may give rise to increased incidences of postoperative intraperitoneal and wound sepsis. Furthermore, the infected biliary tree may be more prone to iatrogenic injury as there is tissue congestion, hyperemia, and increased tissue friability. On the other hand, choledochoscopic views may be worse in cholangitis because of the presence of turbid infected bile, tissue edema, tissue congestion, and inflammatory webs resulting in a higher incidence of retained common bile duct stones.

In deciding whether choledochoscopy should be performed in acute cholangitis, the increased risks of surgical complications have to be balanced against the benefits. Because there is no such information in the medical literature, we decided to determine this scientifically.

Materials and Methods

A prospective study was conducted on 70 consecutive patients with emergency operations done for cholangitis or acute suppurative cholangitis[19,20] with common bile duct stones. During the study, 10 patients who had emergency exploration of common bile ducts for stones were excluded because of: (1) intrahepatic stones (3 patients). Choledochoscopy is valueless for these stones because they are beyond the reach of the instrument, (2) acute obstructive suppurative cholangitis[19,20] with pro-

Submitted for publication: February 2, 1987.

found septicemic shock (5 patients), and (3) serious associated medical diseases, including heart failure (1 patient) and chronic renal failure (1 patient). In the last two groups of patients, we considered it unethical to prolong the operation time and to introduce unknown additional surgical risks by performing choledochoscopy. Three of these patients died soon after operation.

The indication for emergency surgery were: (1) unrelenting cholangitis with high swinging fever and severe abdominal signs (26 patients), (2) failure to respond to conservative treatment (13 patients), (3) cholangitis with septicemia (6 patients), (4) impending septicemic shock with rising pulse and falling blood pressure (16 patients), and (5) transient septicemic shock that responded to preoperative resuscitation (9 patients). These 70 patients who had emergency operations represented 14.2% of all patients treated for cholangitis during the study. The majority of patients responded to conservative treatment with nasogastric aspiration, intravenous fluid, and systemic antibiotics.

All patients received 2 g of cefamandole and 2 mg/kg of gentamicin intravenously before operation. Cholecystectomy was done if the gall bladder was not removed in a previous operation. The duodenum and the head of the pancreas were mobilized by the Kocker maneuver. The common bile duct was opened through a longitudinal supraduodenal incision between two stay stitches after bile was aspirated for aerobic and anaerobic cultures. The duct was thoroughly flushed, Bakes' dilators were passed through the sphincter of Oddi into the duodenum, and Desjardins forceps and Fogarty catheters were passed up and down the duct until the surgeon was satisfied that the duct was clear of stones.

On completion of routine ductal exploration, choledochoscopy was performed with the stay stitches crossed over the rigid Storz choledochoscope (Karl Storz GmbH & Co., Tuttlingen, West Germany). The irrigating fluid was warm normal saline in plastic container placed within a pressure cuff inflated to 300 mmHg suspended 1 m above the patient. If retained stones were detected, they were removed and choledochoscopy repeated until the duct was clear. The common bile duct was then closed around a T-tube. A postexploratory operative T-tube cholangiogram was done before the abdominal wound was closed.

Several additional investigatory procedures were performed on the 70 patients under study.

Common Bile Duct Pressures

A French 5 polyethylene catheter was inserted into the instrument channel of the choledochoscope with the tip protruded for 1 cm beyond the instrument. Side holes were cut in the protruding part of the catheter, which was connected through a three-way stopcock to a water manometer. The choledochoscope was introduced into the common bile duct with the end pointing towards the liver. The zero mark of the manometer was placed at the level of the common bile duct. The stay stitches were crossed to reduce the leak of saline around the instrument. The irrigating fluid was delivered with the pressure cuff completely deflated. The water manometer was filled with normal saline to a height of 60 cm and then opened to the common duct catheter. The common bile duct pressure, that is, the pressure to which the saline column settled, was then recorded. The measurement was repeated twice. The cuff pressure was inflated at steps of 50 mmHg until the cuff pressure reached 300 mmHg. At each pressure increment, the common duct pressure was measured twice. Care was taken to keep the catheter in the center of the common bile duct during measurement of common duct pressure by checking through the choledochoscope. The cuff pressure was then deflated at steps of 50 mmHg until the cuff was completely deflated, and common duct pressure was again measured twice at each pressure decrement. The average of the four values taken at each variation in cuff pressure was taken as the common bile duct pressure.

As this common bile duct pressure measurement was troublesome and time consuming, and the common duct pressures were consistent, we performed it only on the first 20 consecutive patients in this study.

Septicemia

Blood for aerobic and anaerobic cultures were taken routinely before operation and after choledochoscopy. Blood cultures were also taken whenever the patients had chills, rigors, or fever over 39.5 C.

Persistent Cholangitis

The duration of postoperative pyrexia and hospital stay were recorded. Liver function tests were routinely checked before and after operation at intervals of every 3 days.

Bile Cultures

Routine aerobic and anaerobic cultures were taken for gall bladder bile (in patients with intact gall bladders) and common bile duct bile. All culture specimens were sent to the laboratory for plating and culture as soon as possible.

Acute Pancreatitis

Serum amylase levels were determined before operation and after choledochoscopy. A raised serum amylase level of over 7 times the upper limit of normal was taken as diagnostic of acute pancreatitis.

Choledochoscopic Views

After operation, the surgeon filled out a special form giving details on choledochoscopic views. Particular attention was given to assess whether the choledochoscopic examination was complete and whether the duodenal mucosa, the common bile duct, the bifurcation, and the right and the left hepatic ducts were clearly seen. Finally, the surgeon was asked to give his subjective assessment as whether cholangitis affected the choledochoscopic views.

Iatrogenic Injury to the Biliary Tree

Any inadvertent injury to the biliary tree during choledochoscopy, however minor, was recorded.

Value of Choledochoscopy

Choledochoscopy was considered valuable whenever it detected overlooked common bile duct stones left after exploration of common bile duct and whenever it was used in the removal of impacted stones that were not taken out by the conventional methods.

Time Spent in Choledochoscopy

The exact time spent in choledochoscopy was measured and recorded. This did not include time taken to remove impacted stones.

Incidence of Retained Common Bile Duct Stones after Choledochoscopy

Choledochoscopy was considered a failure whenever retained common bile duct stones were detected on postexploratory operative cholangiograms after choledochoscopy or on T-tube cholangiograms performed on the second postoperative week.

Wound and Intraperitoneal Sepsis

All patients with suspected wound or intraperitoneal sepsis were inspected by one assessor. All patients were followed up at 2 and 6 weeks after discharge from hospital and then at 3-month intervals in a specific outpatients clinic. They were contacted by telephone to attend the clinic when they did not turn up. Aerobic and anaerobic cultures were taken for patients with infected wounds. The criteria of Ljungqvist,[21] based on the clinical appearance of the wounds combined with the results of cultures, was used to determine whether the wounds were infected or clean. Wounds with purulent discharge and wounds with serous discharge that gave positive bacteriologic culture were classified as infected. Patients with wounds with serous discharge after they had returned home and, therefore, cultures could not be taken were also included in the infected group.

Operative Mortality

Any patients who died within that hospital admission with emergency operation performed for cholangitis is considered as operative mortality.

Results

We prospectively studied 70 patients with acute cholangitis and acute suppurative cholangitis.[19,20] There were 34 men and 36 women. The ages ranged from 33 to 89 years. The mean age ± SD was 65.8 ± 12.2 years. Forty-seven patients had recurrent pyogenic cholangitis,[22] whereas 23 patients had gall stones in common bile ducts. Sixty-one patients had no previous biliary tract operations, six patients had one each, two patients had two each, and one patient had three.

Common Bile Duct Pressures

The common bile duct pressures (mean ± SD) at cuff pressures of 0, 50, 100, 150, 200, 250, and 300 mmHg were 2.2 ± 0.4, 4.3 ± 1.7, 5.6 ± 1.6, 7.4 ± 2.1, 8.6 ± 2.3, 9.8 ± 2.9, and 13.1 ± 3.9 cm H_2O, respectively.

Even with irrigant delivered at high cuff pressures, the common bile duct pressures never exceeded the safety limit of 25 cm H_2O recommended by Dellinger and his associates.[16] As cholangiovenous reflux only occurs in men at common duct pressure of 30 cm H_2O and above,[16,17] common duct pressure measurement showed choledochoscopy in acute cholangitis and acute suppurative cholangitis to be safe.

Septicemia

Preoperative blood culture was positive for aerobes in 31 patients (44.3%). There was no anaerobes isolated. The most common organisms isolated were *Escherichia coli* (24 patients), *Klebsiella* sp. (2 patients) and *Streptococcus faecalis* (2 patients).

Postcholedochoscopy blood culture was positive for aerobes in 10 patients (14.3%). Again, no anaerobes were isolated. All patients with positive postcholedochoscopy blood cultures had positive preoperative blood cultures, and the organisms isolated were the same. These suggest that the positive postcholedochoscopy blood culture was the result of cholangitis rather than cholangiovenous reflux of infected bile in choledochoscopy.

Persistent Cholangitis

The duration of postoperative pyrexia with body temperature over 37 C (mean ± SD) was 3.3 ± 2.7 days and the duration of postoperative hospital stay was 9.8 ± 5.1 days.

No patients had persistent fever and abnormal liver function tests after surgery to suggest persistent cholangitis.

Bile Cultures

Culture from common bile duct bile was positive in 64 patients (91.4%), with pure aerobes in 38 patients (54.2%), mixed aerobes in 20 patients (28.6%), mixed aerobes and anaerobes in five patients (7.1%), and pure anaerobes in one patient (1.4%). The most common aerobes isolated, either in pure or mixed growths, were *E. coli* in 43 patients (61.4%) *Klebsiella* sp. in 11 patients (15.7%), *S. faecalis* in six patients (8.6%), and *Proteus* sp. in five patients (7.1%). The most common anaerobes isolated were *Clostridium welchii* in four patients (5.7%) and *Bacteroides fragilis* in two patients (2.9%). Anaerobes were found only in patients who had previous biliary tract surgery or in patients with gangrenous cholecystitis.

Nine patients had previous cholecystectomy, and gall bladder bile was taken from 61 patients. Culture from gall bladder bile was positive in 54 patients (88.5%). The organisms isolated from the gall bladder bile were essentially the same as those isolated from the common bile duct bile.

Acute Pancreatitis

A preoperative serum amylase determination was diagnostic of acute pancreatitis in three patients. In two patients, the amylase level remained high after operation. No patients with a normal preoperative serum amylase level had clinical or biochemical evidence of acute pancreatitis develop as a result of choledochoscopy. Choledochoscopy had no adverse effects on the three patients with acute pancreatitis and stones in common bile ducts.

Choledochoscopic Views

Complete choledochoscopic examination was possible in all patients. A good, or at least a satisfactory, view could be obtained in all parts of the biliary tree in all patients. The surgeons considered the choledochoscopic views slightly affected by cholangitis because of the presence of inflammatory webs in five patients (7.1%).

Iatrogenic Injury to the Biliary Tree

There was no inadvertent injury to the biliary tree during choledochoscopy. In fact, the removal of impacted stones under direct vision caused less injury to the biliary tree.

Value of Choledochoscopy

Choledochoscopy detected overlooked common bile duct stones after conventional exploration of the common bile duct in 10 patients (14.3%) and it helped remove impacted stones that were not removed by traditional methods in two patients (2.9%).

Time Spent in Choledochoscopy

The time spent in choledochoscopy (mean ± SD) was 11.2 ± 3.5 minutes.

Incidence of Retained Common Bile Duct Stones after Choledochoscopy

Choledochoscopy failed to detect retained common bile duct stones only in one patient (1.4%) and this retained stone was detected on postoperative T-tube cholangiogram.

Wound and Intraperitoneal Sepsis

Five patients had deep wound infection develop within the first week after operation, whereas two patients had superficial wound infection develop on postoperative days 14 and 17, respectively. There was no intraperitoneal sepsis or abscess. Thus, the overall postoperative sepsis rate was 10%.

Culture from the infected wounds yielded pure aerobes in five patients and mixed aerobes in two patients. The most common organism isolated was *E. coli.*

Operative Mortality

There was no operative mortality in the 70 patients under study.

Discussion

Retained common bile duct stones represent a significant source of morbidity after choledocholithotomy. Although improved methods of retrieval and dissolution are now commonplace,[15] the cost and potential complications to the patient with retained common duct stones mandate the adoption of the most successful methods for complete removal of common duct stones at the initial operation. The conventional techniques of exploration of the common bile duct with the use of forceps, probes, or catheters have one common defect: they are blind procedures that rely on the surgeon's tactile sense alone and the surgeon is unable to see what he is doing. Some surgeons use postexploratory operative cholangiography but most have found it difficult to perform and to intepret and it is often omitted.[3] Moreover, because of its limitations, common bile duct stones can easily be overlooked.[23]

The choledochoscope offers many advantages during common bile duct exploration. By direct inspection, retained stones can be seen, "nonemptying" and "filling defects" on operative cholangiograms clarified, and latent pathologic lesions and anatomic abnormalities discovered. Furthermore, through the operative channel, biopsy of mucosal lesions and removal of impacted stones can be performed.[14,15] It is no wonder that good clinical results have been obtained with choledochoscopy. In the collected series of medical reports on choledochoscopy reviewed by Gartell and McGinn,[2] the incidence of retained common bile duct stones, with only a few exceptional reports,[5-7] was 0–3%.[2] There is no significant difference between the flexible and the rigid choledochoscopes in the reduction of retained stones,[2] despite that the view obtained with the rigid instrument is reported to be less extensive.[24,25]

Reports on intraoperative choledochoscopy focus on its value and safety mainly in elective operations.[1-14] Although the choledochoscopic appearances of the biliary tree in acute cholangitis were described,[4,26] indicating that it was used in acute cholangitis, there is still no solid data to suggest that this practice is safe and effective as there was no separate analysis of results of patients who had such a procedure.

Choledochoscopy in acute cholangitis theoretically increases the risks of operative and postoperative complications. Cholangiovenous reflux has been demonstrated in humans readily at common ductal pressures as low as 30 cm of water. Both bacteria and water-soluble substances pass readily from the bile ducts into the venous system above this pressure.[17] The amount of material refluxing was directly proportional to the pressure achieved in the bile duct,[16,17] resulting in bacteremia, endotoxemia, and septicemia if the refluxed bile was infected. Common duct pressure measurements during rigid choledochoscopy performed by us even at high cuff pressures showed that they never exceeded the safety limit of 25 cm of water recommended by Dellinger and his associates.[16] The performance of cholangiography by syringe injection resulted in common duct pressures that regularly exceeded 40 cm of water, and they frequently reached 80 cm of water transiently.[17] In this respect, choledochoscopy is safer than operative cholangiography and it can be used to replace it,[6,11] or to supplement it,[1,5] in the exploration of common bile ducts.

Our clinical results confirm that choledochoscopy is safe in acute cholangitis and acute suppurative cholangitis.[19,20] Choledochoscopy did not cause septicemia, worsen acute cholangitis, or provoke an attack of acute pancreatitis. There was no injury to the biliary tree by the choledochoscope and there was no operative mortality. The postoperative septic complication rate was acceptably low.[27] The effectiveness of choledochoscopy was not affected by cholangitis and the choledochoscopic views were good. The procedure was simple and the time spent was short. It was valuable in the detection of stones left after conventional methods of exploration of common bile duct, and such overlooked stones occurred in 10–27% of patients.[4,28] It also helped in the removal of impacted stones. Our incidence of retained common bile duct stones of 1.4% compared favorably with that of choledochoscopy in elective surgery.[1-14]

Although choledochoscopy is safe and effective in acute cholangitis and acute suppurative cholangitis,[19,20] it is still questionable whether it should be performed in patients with acute obstructive suppurative cholangitis, patients with serious associated medical diseases, or patients in poor general conditions. We believe that choledochoscopy is inadvisable in these patients with high surgical mortality as it prolongs the operation time and as a result increases the operative risks. The aim of surgery in these patients is to decompress the infected and obstructed biliary trees. Any retained common bile duct stones can subsequently be dealt with by methods of stone retrieval or dissolution[15] when the patients' conditions improve.

Acknowledgments

We thank Mrs. Sylvia Hulse and Dr. Corinna Har for their help in the preparation of this manuscript.

Plasma Cholecystokinin and Pancreatic Polypeptide Response after Radical Pancreatoduodenectomy with Billroth I and Billroth II Type of Reconstruction

KAZUTOMO INOUE, M.D., TAKAYOSHI TOBE, M.D., F.A.C.S., TAKASHI SUZUKI, M.D., RYO HOSOTANI, M.D., MASAFUMI KOGIRE, M.D., AKIRA FUCHIGAMI, M.D., TADASHI MIYASHITA, M.D., KINSUKE TSUDA, M.D.,* and YUTAKA SEINO, M.D.*

From the First Department of Surgery, Faculty of Medicine, Kyoto University, Kyoto, Japan

This study was conducted to elucidate plasma cholecystokinin (CCK) and pancreatic polypeptide (PP) response after pancreatoduodenectomy and to compare response of CCK and PP in patients who had pancreatoduodenectomy with Billroth I and Billroth II type of reconstruction. Basal levels of plasma CCK were significantly lower in patients who had pancreatoduodenectomy (9.6 ± 0.8 pmol/L) than in the control (preoperative patients: 14.6 ± 2.0 pmol/L) probably because of the removal of the entire duodenum due to pancreatoduodenectomy, since vagotomy, which is concomitantly brought about by pancreatoduodenectomy, does not appear to interfere with release of CCK. Significant amounts of CCK (integrated CCK: 497 ± 111 pmol–120 min/L), although less amounts than in the preoperative patients (integrated CCK: 901 ± 167 pmol–120 min/L), were still released in response to oral fatty meal after pancreatoduodenectomy. Plasma CCK response to oral fatty meal was significantly greater in patients who had pancreatoduodenectomy with Billroth I type of reconstruction (integrated CCK: 705 ± 153 pmol–120 min/L) than in patients who had pancreatoduodenectomy with Billroth II type of reconstruction (248 ± 63 pmol–120 min/L). Simultaneous measurement of plasma levels of PP revealed complete abolishment of PP response by pancreatoduodenectomy. Since PP secretion can be produced by vagal stimulation, it is most likely that the decreased PP secretion is due to vagotomy rather than removal of the duodenum and pancreas. Significant amounts of CCK released after pancreatoduodenectomy, in which the main sources of release of CCK are removed, may suggest the compensatory mechanism of the remnant upper small intestine. This study also suggests the necessity of re-evaluating Billroth I type of anastomosis as a physiologic reconstruction procedure for the remnant alimentary tract after pancreatoduodenectomy.

ALTHOUGH SURVIVAL RATES after pancreatoduodenectomy for patients with cancer of the head of the pancreas still remain at low levels, the recent remarkable progress in the diagnostic screening tests, such as computed tomography, ultrasonography, and measurements of serum CA19-9 levels, have made it possible, to a certain extent, to detect a relatively early stage of pancreatic cancer,[1] resulting in the slight but gradual increase of the long-term survival rate after pancreatoduodenectomy. Cholecystokinin (CCK) is a well-known gastrointestinal hormone that plays a physiologic role not only in stimulating pancreatic enzyme secretion[2-4] and insulin release[5] but also in exerting a trophic effect on the pancreas.[6] It is, therefore, of great significance to investigate the plasma CCK response in patients with pancreatoduodenal resection to assess the exocrine and endocrine function of the remnant pancreas and to compare plasma CCK responses after different reconstructive procedures in pursuit of the most physiologically pertinent reconstruction of the alimentary tract after pancreatoduodenectomy.

Assumedly, CCK could exert an important role for the modulation of the function of the remnant pancreas even after pancreatoduodenal resection, but no information is available as to whether CCK is released into circulation after pancreatoduodenectomy, which removes the main sources[7] of release of CCK.

The current study was done to clarify changes in plasma CCK levels after pancreatoduodenectomy with special reference to the comparison of plasma CCK response after reconstruction of the alimentary tract with

Billroth I type of Reconstruction

Billroth II type of Reconstruction

FIG. 1. Two types of reconstruction method for the alimentary tract after radical pancreatoduodenectomy in our department.

Billroth I and Billroth II type of anastomosis, both of which have been performed in our department (Fig. 1).

Simultaneous measurement of plasma levels of pancreatic polypeptide (PP), which plays a physiologic role for inhibition of exocrine pancreatic secretion,[8] was also done.

Materials and Methods

Eleven patients (8 men and 3 women) who had had pancreatoduodenectomy, ranging in age from 35 to 72 years with a median age of 56 years, were investigated. Included were seven patients with cancer of the head of the pancreas, two patients with cancer of the intrapancreatic common bile duct, one patient with cancer of papilla of Vater, and one patient with cancer of the duodenum, respectively. Radical pancreatoduodenectomy had been performed on these patients with *en bloc* resection of the head of the pancreas, entire duodenum, 5 cm of the upper jejunum, and distal half of the stomach, followed by cholecystectomy. The alimentary tract had been reconstructed either with Billroth I type of anastomosis (6 patients) or with Billroth II type of anastomosis (5 patients) (Fig. 1). Postoperative periods of these patients were 1 month (1 patient), 2 months (1 patient), 3 months (1 patient), and 12 months (3 patients) among patients with Billroth I type of reconstruction, and 1 month (1 patient), 2 months (1 patient), 3 months (1 patient), 6 years and 9 months (1 patient), and 6 years and 11 months (1 patient) among patients with Billroth II type of reconstruction, respectively. Postoperative courses in these 11 patients had been uneventful. Seven preoperative patients with early gastric cancer (2 men and 5 women), ranging in age from 51 to 71 years (mean: 62 years), were also studied as a control group for comparison with patients who had pancreatoduodenectomy. There was no pyloric stenosis in these preoperative patients.

After a 14-hour fast, patients who had pancreatoduodenectomy and preoperative patients were ingested with 200 mL of a fatty meal (chemically defined diet containing 14 g of fat; Clinimeal, Eisai Company, Japan). Peripheral blood samples were drawn before and serially at 10-minute intervals for 120 minutes after Clinimeal. Samples of blood were collected in tubes containing 50 KIU of Trasylol and 10 U of heparin per milliliter of blood and centrifuged at 3000 rpm with the constant temperature at 4 C for 15 minutes. The plasma was separated and stored at −20 C for future measurement of CCK and PP by specific radioimmunoassays.

Radioimmunoassay of CCK

Plasma levels of CCK was measured by means of a sensitive and specific radioimmunoassay for CCK-33 and CCK-39 that was developed by Thompson and Rayford,[3,9–12] using the CCK antibody (UT132), generously provided by Professor Phillip L. Rayford (Department of Physiology, University of Arkansas Medical Sciences, Little Rock, AR). The validation and details of

CCK radioimmunoassay conducted in our laboratory[13] are as follows.

CCK variant (CCK-39), supplied by Professor V. Mutt (Karolinska Institute, Sweden), was labeled (2.5 μg) with ^{125}iodine (1 mCi) by the chloramine-T method (25 μg/10 μL of chloramine T in 0.5 M potassium phosphate [PB] pH 6.0) for 60 seconds, followed by 62.5 μg/25 μL of sodium metabisulfite in 0.15 M PB. Labeled hormone was separated from other contaminants on an 11 × 0.9-cm Sephadex G-25 fine column (Pharmacia Fine Chemicals, Piscataway, NJ) eluted with 0.15 M PB containing 1 M NaCl (pH 6.0). ^{125}I-CCK-39 was further purified on a 4-cm column (Pasteur pipette) containing cellulose CF-11 (Whatman, Clifton, NJ) immediately before being used as a labeled tracer. Assay tubes were prepared with 200 μL of standards or plasma samples, 300 μL of phosphate buffer (0.02 M sodium phosphate, 0.15 M NaCl, 0.1% sodium azide, 0.5% normal rabbit serum, pH 6.8), 100 μL of antibody solution (final dilution 1:75,000), 100 μL of 0.1 M ethylenediaminetetraacetic acid (EDTA), and 100 μL of Trasylol (250 KIE/tube). The assay tube was then incubated for 24 hours at 4 C. Labeled CCK-39 (200 μL, 8000 cpm) was added to each tube and incubated for another 48 hours. The assay was terminated by an overnight incubation with goat antirabbit-γ globulin serum (Organon Teknika N.V., Malvern, PA).

The antibody bound 25–30%, 30–35%, and more than 75% of labeled CCK-39 at the final dilution of 75,000, 50,000, and 500, respectively, and nonspecific binding was less than 2%. Ten per cent inhibition of maximum binding (detection limit) was 1.6 ± 0.2 fmol/tube of standard CCK-33 and 50% inhibition (ID_{50}) was 13.4 ± 0.9 fmol/tube in five different assays. The intraassay variance was 8% and interassay variance was 10%. In this study, all samples were measured in duplicate in the same assay, and plasma CCK-33 levels were determined using standards containing 200 μL of hormone-free human plasma. When graded doses of CCK-33, CCK-39 (Professor V. Mutt), CCK-op (Dr. N. Yanaihara, Shizuoka, Japan), and synthetic human gastrin (G-17, Sigma, St. Louis, MO) were measured in the assay system, the slopes of the dose-response curve generated by CCK-33 and CCK-39 were −2.3 and −2.0, respectively. Estimation of ID_{50} revealed that CCK-33 and CCK-39 were almost equally potent. In contrast, the slopes of the dose-response curve for G-17 and CCK-op were −0.58 and −0.46, respectively, and the potency of both peptides was less than 0.5% when compared with that of CCK-33 at ID_{50}. No cross-reactivity was observed with structurally unrelated gastrointestinal peptides such as secretin, GIP, VIP, substance p, PYY, neuromedin C, or GRP. Serial dilutions of dog postprandial plasma (25–200 μL) and duodenal extracts (1:200–1:3200) produced parallel dose-response curve compared with that of standard CCK-33.

The comparison of dose-response curves generated by CCK standard diluted with or without 200 μL of hormone-free plasma clarified that the slopes and ID_{50} of CCK standard diluted with hormone-free dog plasma, with hormone-free human plasma, and with buffer (without hormone-free plasma) are −2.0 and 11.1 fmol/tube, −1.8 and 15.1 fmol/tube, and −1.8 and 9.9 fmol/tube, respectively, demonstrating that this assay system is free from the influence of interference substances in the plasma.

Radioimmunoassay of PP

Plasma PP levels were measured by specific radioimmunoassay[14] using rabbit anti-h PP serum, kindly donated by Dr. R. E. Chance (Lilly Research Laboratories, Eli Lilly Co., Indianapolis, IN).

The results of this study are expressed as mean ± SEM. Student's paired or unpaired t-test was used to analyze the data for statistical differences. Differences with a p value of less than 0.05 were considered significant.

Results

Basal Plasma Levels of CCK

Mean basal plasma levels of CCK in the pancreatoduodenectomy group (11 patients) (9.6 ± 0.8 pmol/L) were significantly lower than those observed in the control group (7 preoperative patients) (14.6 ± 2.0 pmol/L). No significant difference was noted between mean basal plasma CCK levels in the pancreatoduodenectomy group reconstructed with Billroth I type of anastomosis (6 patients) (8.9 ± 0.6 pmol/L) and Billroth II type of anastomosis (5 patients) (10.4 ± 1.0 pmol/L).

Plasma CCK Response

In the control group (preoperative patients), in response to oral fatty meal, incremental values of CCK (ΔCCK) were significantly increased to 3.7 ± 1.3 pmol/L at 5 minutes, attained the peak of 11.7 ± 3.3 pmol/L at 20 minutes, and then remained significantly elevated up to 120 minutes. In the pancreatoduodenectomy group, ΔCCK values were also significantly elevated after oral fatty meal, showing the peak value of 7.2 ± 1.5 pmol/L at 20 minutes. Although ΔCCK values remained significantly elevated throughout the study, plasma CCK response in the pancreatoduodenectomy group was lower than that observed in the preoperative group (Fig. 2). The integrated CCK in the pancreatoduodenectomy group (497 ± 111 pmol-120 min/L) was significantly less than that noted in the control group (901 ± 167 pmol-120 min/L) (Fig. 3).

Plasma CCK response to oral fatty meal was com-

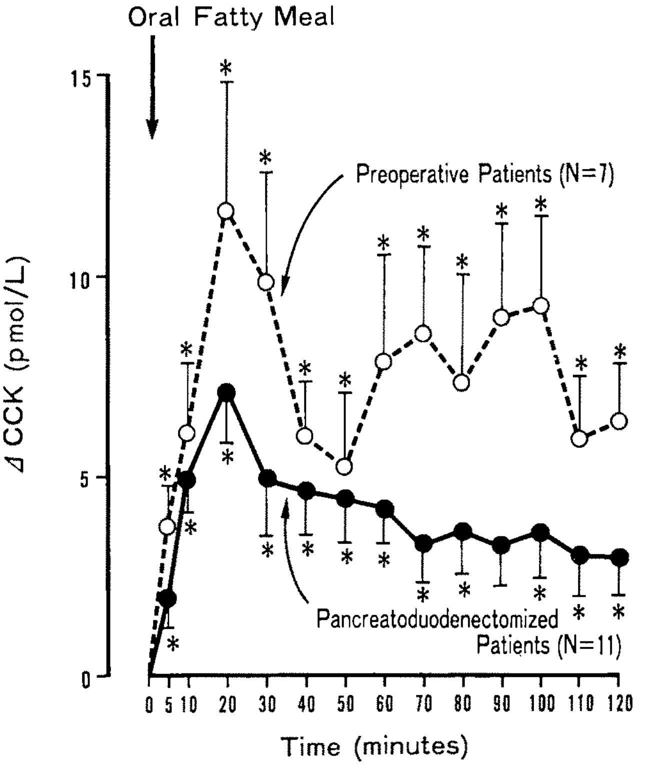

FIG. 2. Comparison of the plasma CCK response to oral fatty meal in preoperative patients and patients who had pancreatoduodenectomy. Asterisks indicate significant elevation above basal.

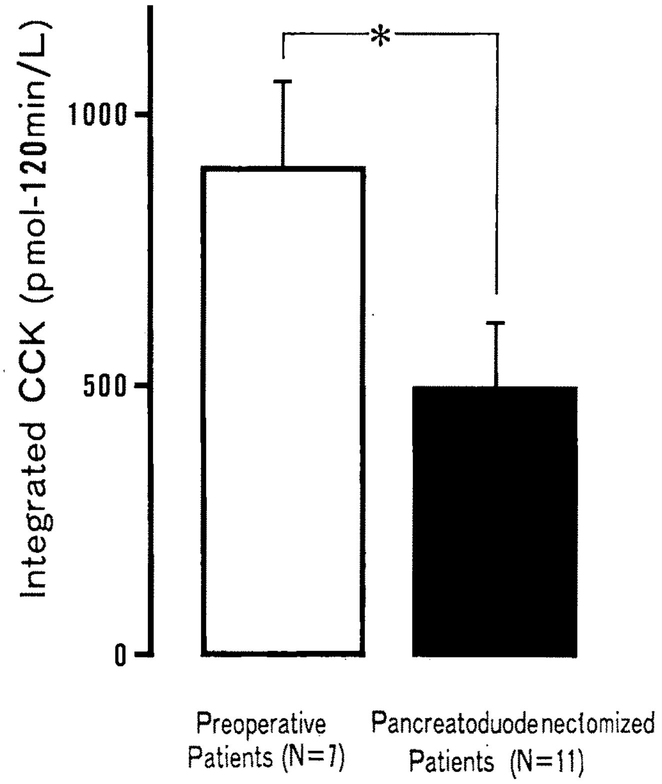

FIG. 3. Integrated CCK in preoperative patients and patients who had pancreatoduodenectomy. Asterisk indicates significant difference in integrated CCK between preoperative patients and patients who had pancreatoduodenectomy.

pared among patients who had pancreatoduodenectomy with Billroth I and Billroth II type of anastomosis (Fig. 4). Patients with Billroth I type of anastomosis showed a rapid and greater plasma CCK response when compared with plasma CCK response in patients with Billroth II type of anastomosis. In patients with Billroth I type of reconstruction, ΔCCK values rose significantly to the maximum of 10.8 ± 1.7 pmol/L at 20 minutes and then gradually began to fall, however, remaining elevated up to 100 minutes. On the other hand, patients with Billroth II type of reconstruction showed a delayed and lower plasma CCK response compared with that noted in patients with Billroth I type of reconstruction; significant increase in ΔCCK values was achieved at 30, 40, 50, 60, 110, and 120 minutes after oral fatty meal (Fig. 4). The integrated CCK was significantly greater in patients who had pancreatoduodenectomy with Billroth I type of reconstruction (705 ± 153 pmol–120 min/L) than in patients who had pancreatoduodenectomy with Billroth II type of reconstruction (248 ± 63 pmol–120 min/L) (Fig. 5).

Basal Plasma Levels of PP

The mean basal plasma level of PP in the control group was 35 ± 8 pmol/L. In contrast, basal plasma levels of PP were undetectable (below detection limit) in

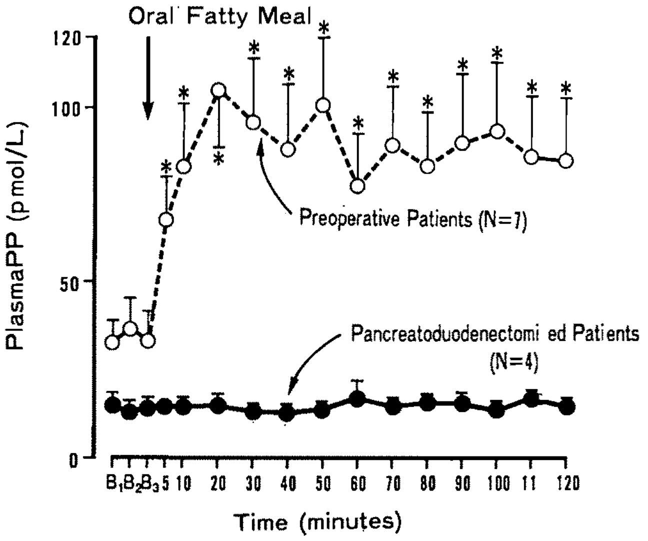

FIG. 6. Comparison of the plasma PP response to oral fatty meal in preoperative patients and patients who had pancreatoduodenectomy. Asterisks indicate significant elevation above basal.

seven of 11 patients with pancreatoduodenal resection. The mean basal plasma level of PP in four patients in whom PP levels were detectable (16 ± 1 pmol/L) was significantly less than that found in the control group (Fig. 6).

Plasma PP Response

Plasma PP in preoperative patients showed a rapid and significant increase in response to oral fatty meal; significant elevation was achieved at 5 minutes (68 ± 14 pmol/L) and remained significantly elevated up to 120 minutes. On the contrary, patients with pancreatoduodenal resection did not show any increase in plasma PP levels after ingestion of a fatty meal (Fig. 6).

Discussion

The role of hormonal factors, especially that of CCK, is supposedly of great importance in modulating the exocrine and endocrine function[2–6] of the remnant pancreas after pancreatoduodenal resection that is performed on patients with periampullary cancer, since radical pancreatoduodenectomy is inevitably accompanied by vagotomy. The effect of vagotomy on gastrointestinal hormones has been widely documented.[15–21] To evaluate whether CCK release is under vagal control, Guzman and colleagues[17] electrically stimulated the vagus nerves of anesthetized dogs and found increased pancreatic protein secretion, but no increase in plasma levels of CCK, indicating that CCK release is not under vagal control and that vagal stimulation of pancreatic secretion occurs through a mechanism independent of CCK. They have also demonstrated that vagotomy has no effect on the release of CCK.[18] This observation is inconsistent with reports by Fried and colleagues who have shown that CCK secretion in response to intraduodenal oleate[19,20] or to exogenous bombesin[20] or CCK[20] was not significantly affected by vagotomy. On the other hand, PP secretion is predominantly mediated through the vagal cholinergic pathways. Modlin and colleagues[21] have demonstrated that the release of PP is inhibited to a significantly greater extent by vagotomy than by atropine. Prominent decrease of PP secretion by vagotomy has been also confirmed by Guzman and colleagues[18] and by Fried and colleagues.[20] However, to our knowledge, radioimmunoassay measurement of plasma levels of CCK and PP after pancreatoduodenectomy has not been performed. The current study revealed that basal concentrations of plasma CCK were significantly lower in patients who had pancreatoduodenectomy than in the preoperative patients. This relatively low basal level of plasma CCK after pancreatoduodenal resection could be possibly attributed to the elimination of the entire duodenum in which CCK producing cells are most numerously distributed,[7] since vagotomy does not appear to interfere with release of CCK. Despite the low fasting secretion of CCK in patients who had pancreatoduodenectomy, this study demonstrates that significant amounts of CCK, although less amounts than in the preoperative patients, are still released postprandially even after pancreatoduodenectomy, which removes the main sources of release of CCK, suggesting that this phenomenon may reflect the compensatory mechanism of the remnant upper small intestine. Plasma responses of other hormonal factors, such as secretin, gastrin, and gastric inhibitory polypeptide, in patients who had pancreatoduodenectomy have also been documented; diminished secretin response to the ingestion of hydrochloride solution,[22] food,[23] no response of gastrin to intravenous infusion of arginine,[22] and almost the same response of gastric inhibitory polypeptide to oral glucose as observed in the control group.[24] In these reports, however, reconstruction of the alimentary tract after pancreatoduodenectomy has been performed with Billroth II type of anastomosis (modified Child method).

There have been two types of reconstruction procedure for the remnant alimentary tract after pancreatoduodenectomy; Billroth I type (Cattell[25] and Imanaga[26]) and Billroth II type (Whipple[27] and Child[28]).

In our department, we have been performing Billroth I type of anastomosis as well as Billroth II type of anastomosis after pancreatoduodenal resection as represented on Figure 1. One of the original aspects of Billroth I type of reconstruction procedure in our department lies in the retrocolic approach for the anastomosis of the remnant alimentary tract after pancreatoduodenectomy. The unique Billroth I type of reconstruction procedure after pancreatoduodenectomy was started about 7 years ago in our department, since it was conceivable that the passage of food through the entire remnant upper small intestine was more physiologic than food bypassing the upper portion of the remnant small intestine in view of the release of gastrointestinal hormones, which presumably play a significant role in the modulation of the function of the remnant alimentary tract.

The current study first did a comparative study on the plasma response of gastrointestinal hormones in patients who had pancreatoduodenectomy with Billroth I type and II type of anastomosis. The interesting phenomenon that plasma CCK response was significantly greater in patients who had pancreatoduodenectomy with Billroth I type of anastomosis than in patients with Billroth II type of anastomosis may support the hypothesis that after pancreatoduodenectomy, Billroth I type of reconstruction method is a more physiologic procedure than Billroth II type of reconstruction because CCK could exert a trophic effect[6] on the remnant pancreas as well as play an important role in the regulation of exocrine[2-4] and endocrine[5] function. Approximately 100 pancreatoduodenal resections have been performed in our department over the last 7 years from 1979 to 1985. Comparative studies on surgical complications after pancreatoduodenectomy in our department revealed that there was no significant difference between Billroth I and Billroth II type of reconstruction in both morbidity and mortality after pancreatoduodenectomy, except that intermittent fever due to the late stage of biliary infection was more frequently observed after Billroth II type of reconstruction.

It has been controversial relating to the molecular forms of CCK in the circulation and physiologic importance of CCK-33 and CCK-8. Recent studies by Solomon et al.[29] and Konturek et al.[4] have clarified that larger molecular forms of CCK is quantitatively the most important mediators of CCK action on the pancreas. The antibody used in this study has its greatest affinity for larger forms of CCK (CCK-33 and CCK-39) and has little or no affinity for the smaller forms of this peptide.[3,9-13] The same CCK antibody that was used in the current study has been proved to inhibit not only the stimulatory effects of pure CCK and extracts of the duodenum on gallbladder contraction[11] but also the bioactivity of both exogenously administered and endogenously released CCK on the pancreas,[3] supporting the concept that larger forms of CCK are mediators of the two major biologic actions of CCK.

In contrast to plasma CCK response, pancreatoduodenectomy completely abolished plasma PP response. Basal plasma levels of PP were even undetectable in seven of 11 patients who had pancreatoduodenectomy. Since PP secretion is to a great extent mediated through the vagal cholinergic pathways,[18,20,21] it is most likely that the decreased PP secretion is due to vagotomy rather than removal of the duodenum and pancreas. PP originates from cells localized almost exclusively in the pancreas.[30] Regional differences in PP distribution exist, with PP found predominantly in the uncinate process and head of the pancreas.[31] Total pancreatectomy has been reported to abolish the increase in circulating PP seen after a meal, which led to the suggestion that the pancreas is the only site of PP release.[32] The complete abolishment of PP release even after pancreatoduodenectomy, which preserves most of the left lobe (body and tail) of the pancreas, might be partly attributed to the predominant distribution of PP cells in the right lobe of the pancreas.

In conclusion, this study demonstrates that significant amounts of CCK, but not PP, are released even after pancreatoduodenectomy, which removes the main sources of release of CCK, suggesting the compensatory mechanism of the remnant upper small intestine. Significantly greater CCK response in patients who had pancreatoduodenectomy with Billroth I type of reconstruction than in patients with Billroth II type of reconstruction might prompt us to re-evaluate Billroth I type of anastomosis as a more physiologic reconstruction procedure for the alimentary tract after pancreatoduodenectomy.

Acknowledgments

We are grateful to Professor Viktor Mutt (Karolinska Institute, Sweden) and Dr. Kazuhiko Tatemoto (Stanford University School of Medicine, Stanford, CA) for supplying us with the pure CCK-33 and CCK-39. We are also grateful to Professor Phillip L. Rayford (University of Arkansas Medical Sciences, Little Rock, AR) for his generous gift of the CCK antibody (UT 132).

THE NYHUS/NELSON™ NASOGASTRIC TUBE FOR GASTRIC DECOMPRESSION AND JEJUNAL FEEDING

The NYHUS/NELSON™ TUBE inserted nasogastrically during abdominal operations is used for simultaneous gastric decompression and enteral feeding. Its proven twin balloon design facilitates passage of the tube through the retroperitoneal duodenum. The risks of enterotomy are then avoided. Your patient is protected against gastric distention and reflux of enteral alimentation fluids. Advantages of early post-op feeding with the NYHUS/NELSON™ TUBE include significant metabolic benefits, weight maintenance, and shorter hospital stays.

Send the coupon below to receive more information on how the NYHUS/NELSON™ TUBE can help save costs and benefit your patients.

Also Available
Nyhus/Nelson™
Gastrostomy Tube

U.S. Patent No. 4,368,739

ce the tip of the tube has been advanced the second portion of the duodenum, the ximal balloon, which is still in the stomach, n be grasped and pushed through the orus. As the proximal balloon approaches second portion of the duodenum the tal balloon can be grasped at the ligament Treitz and the tip of the tube advanced into jejunum.

CHANGE THE FACE OF PAIN

The following is a brief summary only. Before prescribing, see complete prescribing information in TYLOX® (oxycodone and acetaminophen) labeling.

CONTRAINDICATIONS: TYLOX (oxycodone and acetaminophen) capsules should not be administered to patients who have previously exhibited hypersensitivity to any component.
WARNINGS: Contains sodium metabisulfite, a sulfite that may cause allergic-type reactions including anaphylactic symptoms and life-threatening or less severe asthmatic episodes in certain susceptible people. The overall prevalence of sulfite sensitivity in the general population is unknown and probably low. Sulfite sensitivity is seen more frequently in asthmatic than in nonasthmatic people.

PRECAUTIONS: General: *Head Injury and Increased Intracranial Pressure:* The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions, or a pre-existing increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.
Acute Abdominal Conditions: The administration of TYLOX (oxycodone and acetaminophen) capsules or other narcotics may obscure the diagnosis or clinical course in patients with acute abdominal conditions.
Special Risk Patients: TYLOX capsules should be given with caution to certain patients such as the elderly or debilitated, and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, and prostatic hypertrophy or urethral stricture.

Information for Patients: Oxycodone may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. The patient using TYLOX capsules should be cautioned accordingly.
Drug Interactions: Patients receiving other narcotic analgesics, antipsychotics, anti-anxiety agents, or other CNS depressants, including alcohol, concomitantly with TYLOX capsules, may exhibit additive CNS depression due to the oxycodone component. When such combined therapy is contemplated, the dose of one or both agents should be reduced. The use of MAO inhibitors or tricyclic antidepressants with oxycodone preparations may increase the effect of either the antidepressant or oxycodone. The concurrent use of anticholinergics with oxycodone may produce paralytic ileus.

CLASSIFIED AD SECTION

Classified advertising is available in **ANNALS OF SURGERY** for those recruiting personnel or interested in obtaining positions. Display space also is available for those desiring greater visibility or more space for their message.

Classified ad copy, like other advertising copy, will be reviewed for approval prior to publication.

Classified Rates: $9.00 per line or fraction of line. The average line will be 40 characters.

Box Numbers: Replies may be directed via Box # to J.B. Lippincott Company, at an extra charge per insertion of $6.50 to cover handling costs in forwarding such replies to the advertiser.

How to Order: Send typewritten text copy for the ad with remittance in full to:

GENERAL SURGEON—BC/BE, with broad-based training (especially in areas of trauma, burns, pediatric and non-cardiac thoracic surgery) to join a 38-doctor multi-specialty clinic with three well-established general surgeons. Modern forward looking hospital with excellent staff and superb equipment. Located in a southern Wisconsin college town of 50,000 near Chicago, Milwaukee and Madison. Guaranteed salary initially but optional transition to compensation based on production. Position available for June, 1988 or sooner. Contact: **James F. Ruethling, Administrator, Beloit Clinic, S.C., 1905 Huebbe Parkway, Beloit, WI 53511, Ph. 608/364-2200.**

GENERAL SURGEON for full time faculty position with training and principal interest in the field of nutrition. Gastrointestinal and/or encodrine surgery. Department of Surgery, Medical College of Ohio. Address inquiries to **Neil R. Thomford, M.D., Chairman, Department of Surgery, Medical College of Ohio, C.S. 10008, Toledo, OH 43699.** The Medical College of Ohio is an equal opportunity employer.

PLASTIC & RECONSTRUCTIVE SURGEON: 200+ member multi-specialty group seeks BC/BE specialist; large primary, secondary, and tertiary practice with substantial referrals; adjacent to 500 bed hospital with superior intensive care unit; free-standing ambulatory surgery center; affiliated with medical school, part time faculty appointments available; located in upper midwest tri-college community of 130,000; 35 minutes from clean lake region; will pay travel expenses for physician and spouse to travel. Send CV in confidence to **Charles B. Anderson, M.D., P.O. Box 2067, Fargo, ND.**

TO THE FACE OF RELIEF

TYLOX® CII capsules
(OXYCODONE & ACETAMINOPHEN)

THE POTENCY OF PERCODAN®* WITHOUT ASPIRIN

*Percodan is a registered trademark of DuPont Pharmaceuticals.

Usage in Pregnancy: Pregnancy Category C. Animal reproductive studies have not been conducted with TYLOX. It is also not known whether TYLOX can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. TYLOX should not be given to a pregnant woman unless in the judgement of the physician, the potential benefits outweigh the possible hazards.
Nonteratogenic Effects: Use of narcotics during pregnancy may produce physical dependence in the neonate.
Labor and Delivery: As with all narcotics, administration of TYLOX to the mother shortly before delivery may result in some degree of respiratory depression in the newborn and the mother, especially if higher doses are used.
Nursing Mothers: It is not known whether the components of this drug are excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TYLOX is administered to a nursing woman.
Pediatric Use: TYLOX capsules should not be administered to children.
ADVERSE REACTIONS: The most frequently observed adverse reactions include lightheadedness, dizziness, sedation, nausea, and vomiting. These effects seem to be more prominent in ambulatory patients than in non-ambulatory patients, and some of these adverse reactions may be alleviated if the patient lies down. Other adverse reactions include allergic reactions, euphoria, dysphoria, constipation, skin rash, and pruritus. At higher doses oxycodone has most of the disadvantages of morphine including respiratory depression.
DRUG ABUSE AND DEPENDENCE: TYLOX (oxycodone and acetaminophen) capsules are a Schedule II controlled substance. Oxycodone can produce drug dependence of the morphine type and, therefore, has the potential for being abused. Psychic dependence, physical dependence, and tolerance may develop upon repeated administration of TYLOX capsules, and they should be prescribed and administered with the same degree of caution appropriate to the use of other oral narcotic-containing medications.

Full directions for use should be read before administering or prescribing.

For information on symptoms and treatment of overdosage, see full prescribing information. 12/19/86

CASE # 24 **AGE:** 55 **SEX:** FEMALE

DIAGNOSIS: CECAL CARCINOMA

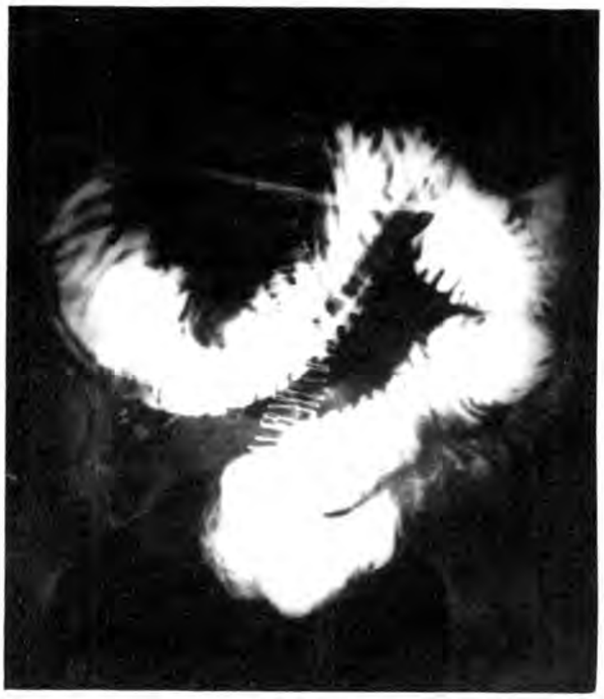
SYMPTOMS: ANEMIA (Hg 6 gm/dl)

OPERATION: RIGHT HEMICOLECTOMY & GASTROSTOMY

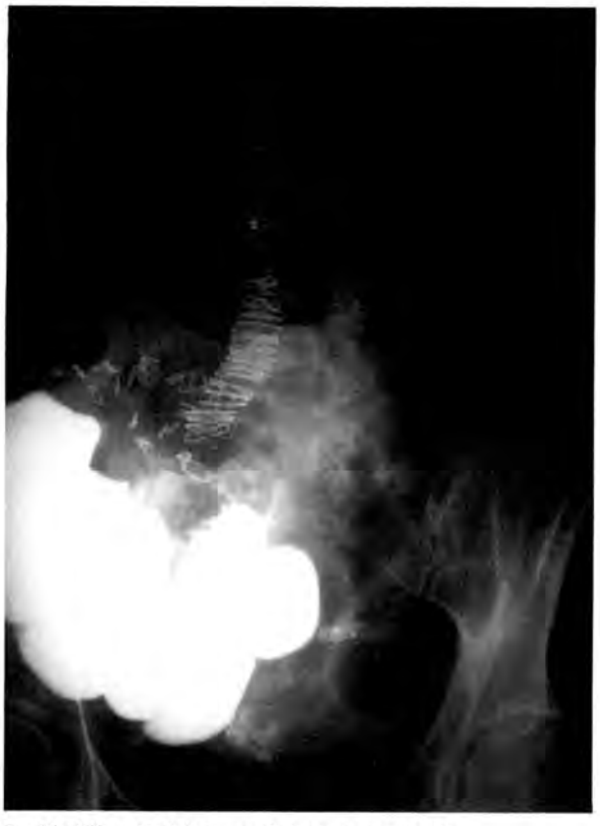
The patient had a right hemicolectomy with stapled (U.S. Surgical Corp) anastomosis and fascia closure and a MOSS® gastrostomy tube. The stomach and proximal duodenum were aspirated, with immediate simultaneous feeding into the distal duodenum.

Barium feeding 5 hours postop documented adequate motility. The deliberate excess was totally removed. No contrast (i.e.: excess feeding) escaped efficient aspiration within the proximal duodenum, to reflux into the stomach. (Figure A) Serial motility study showed barium had traversed the anastomosis and colon, and already was exiting in a spontaneous bowel movement by 21 hours postop. (Figure C)

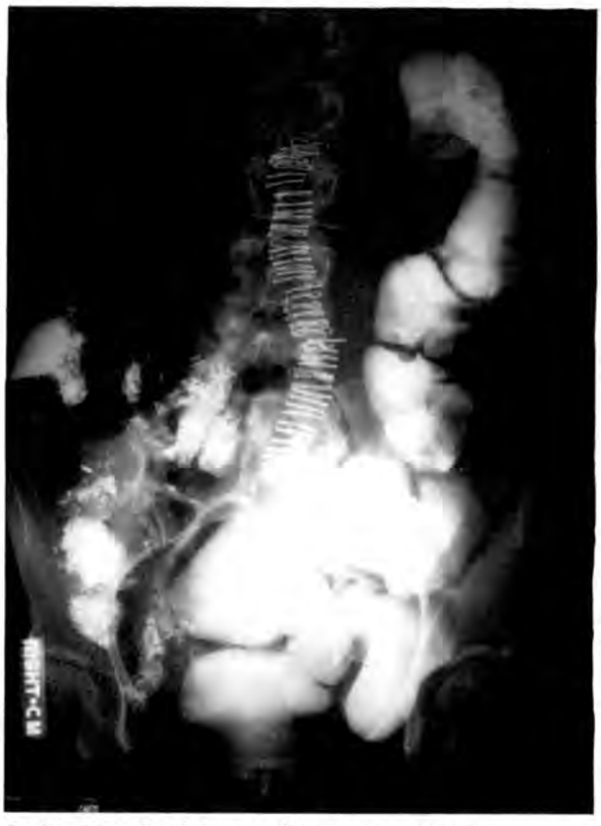
She received 300 ml/hr of Vivonex TEN (Norwich Eaton Pharm), absorbed 5,000 kcal the initial 20 hours, and then tolerated a general diet. She was the 4th patient discharged uneventfully 24 hours after bowel resection and reanastomosis.



A. Study @ 5 minutes (5 hours postop).
Note efficient removal of all excess barium, with none reaching the stomach.



B. Motility @ 4 hours (9 hours postop).
All barium is within the ileum.



C. Motility @ 16 hours (21 hours postop).
Barium is exiting in a spontaneous bowel movement.

"...Rarely in the modern textbook does one find the unique combination of a masterful command of the English language, the superb organization of the book itself, and the combined textbook atlas concept so well written and prepared by a sole author who fearlessly commits his opinions in writing..."*

Colon and Rectal Surgery

By Marvin L. Corman, M.D.

Winner of the 1985 American Medical Writers Association Medical Book Award in the Physician's Category

*"...extremely well-written, readable, and highly informative of the state-of-the-art of colon and rectal surgery...exceptional..."—*Diseases of the Colon and Rectum*

Helps you manage all aspects of diseases and surgery of the anus, rectum and colon

COLON AND RECTAL SURGERY is a comprehensive and abundantly illustrated text/atlas providing an organized approach to the diagnosis and treatment of the more common conditions affecting the anus, rectum and colon. Many esoteric and unusual problems are also discussed; and each chapter contains an extensive bibliography directing you to further study.

". . . uniform excellent quality throughout . . . The extensive illustrations, some of which are in color, are extremely helpful. The bibliography is unusually complete and contains many references to recent articles. The author is to be congratulated for the wealth of material that he has been able to encompass in this one volume . . ."—The New England Journal of Medicine

Unique single authorship . . . insightful commentaries

The single authorship, unique in so comprehensive a text, allows Dr. Corman to emphasize procedures for which he has considerable clinical experience, and to offer insightful commentaries placing concepts into their proper perspective.

". . . it is refreshing to be exposed to the perspective of a mature and experienced colon and rectal surgeon who has added the personal touch to a surgical text in good taste, regardless of whether the reader agrees with the conclusion . . ."
—Diseases of the Colon and Rectum

A superior atlas of surgical techniques

Every chapter is packed with superb illustrations of surgical techniques, showing exactly what you need to know about the full range of colon and rectal conditions. 16 full-color illustrations show the appearance of various conditions such as ulcerative colitis, melanosis coli, pruritus ani, and extramammary Paget's disease. Sharp x-rays, photomicrographs, and tables amplify the text.

". . . more completely enhanced with photographs, drawings, and roentgenograms than any other textbook on the market . . ."
—Mayo Clinic Proceedings

Other important features

- emphasizes reconstructive anorectal surgery—for which Dr. Corman is well known
- fully covers management of cancer and inflammatory bowel disease
- describes in clear and precise detail complex anorectal and colon operations
- contains in-depth discussions of incontinence, ostomy complications and their management, and dermatologic anal problems.

Large 8" x 10" Format. 784 Pages. 818 Illustrations, 16 in Full Color. 49 Tables. 1984. $95.00.

The Comparative Influence of Prophylactic Antibiotics on the Prothrombin Response to Warfarin in the Postoperative Prosthetic Cardiac Valve Patient

Cefamandole, Cefazolin, Vancomycin

DAVID M. ANGARAN, M.S., VIRGIL C. DIAS, PHARM.D., KIT V. AROM, M.D., WILLIAM F. NORTHRUP, M.D., THOMAS G. KERSTEN, M.D., WILLIAM G. LINDSAY, M.D., and DEMETRE M. NICOLOFF, M.D.

From the United Hospital Heart Institute, United Hospital, St. Paul, Minnesota

A prospective randomized trial was conducted comparing the effect of three antibiotics: cefamandole (CM), cefazolin (CZ), and vancomycin (V), used as prophylaxis for prosthetic valve surgery, on the prothrombin (PT) response to warfarin (W) on the third day of anticoagulant therapy. Twenty patients, with normal preoperative PTs, were randomized to each antibiotic. Their PTs were not significantly different at 2 hours after operation and the morning before W was begun. The three groups received similar W doses for 2 days, and the PT, as percentage of activity, on the morning of the third day demonstrated that V (51 ± 18%) was significantly greater ($p < 0.005$) than CM (29 ± 14%) or CZ (38 ± 18%). CM had a significantly greater percentage of change in PT (64 ± 14%, $p < 0.0001$) from the first to third day than either CZ (51.1 ± 18%) or V (44.6 ± 19%). CM also had a greater number of patients (6) with PTs ≥ 30 seconds on day 3 than either CZ (1) or V (1). The antibiotic influence on the PT response to W in this study is ranked as CM > CZ > V.

THE FIRST-GENERATION cephalosporins (*e.g.*, cephalothin, cefazolin) have been widely used as the antibiotic of choice for prophylaxis of surgical infections. These antibiotics have been reported to cause hypoprothrombinemia in patients receiving long-term antibiotic therapy with a poor dietary intake or in renal failure.[1-3] More recently, the second-generation cephalosporins, such as cefamandole, have enjoyed wide popularity in prophylaxis of heart surgery because of their extended gram-negative spectrum and activity against *Staphylococcus aureus* and *Staphylococcus epidermidis*. Cefamandole contains the 1-N-methyl-5-thiotetrazole (MTT) group that has been implicated as a cause of accelerated prothrombin (PT) depletion associated with episodes of both major and minor bleeding.[4,5] Vancomycin, a noncephalosporin antibiotic with only a gram-positive spectrum, has not been implicated as a cause of hypoprothrombinemia.[6]

For patients who have prosthetic valve replacement surgery, adequate anticoagulation is of vital importance in prevention of thromboembolic complications. The type of prophylactic antibiotic administered to these patients during and after surgery could influence the response to subsequent warfarin anticoagulation therapy.

We have reported a retrospective investigation comparing the PT response to warfarin in patients undergoing prosthetic valve surgery who received either cefamandole or vancomycin. This study indicated that patients receiving cefamandole had a significantly greater hypoprothrombinemic response after the first 2 days of warfarin therapy when compared with patients administered vancomycin.[7]

To confirm this retrospective work, we conducted the following prospective randomized, open-label trial comparing the effect of cefamandole, cefazolin, and vancomycin as prophylactic antibiotics on the PT response to warfarin in patients who had prosthetic valve surgery.

Methods

Sixty patients who were scheduled to have cardiac valve replacement surgery were prospectively assessed and randomly assigned by a random number table to receive either cefamandole, cefazolin, or vancomycin for surgical prophylaxis. All patients with a history of either a penicillin or cephalosporin allergy were assigned to receive vancomycin. The study was approved by the

Submitted for publication: February 3, 1987.

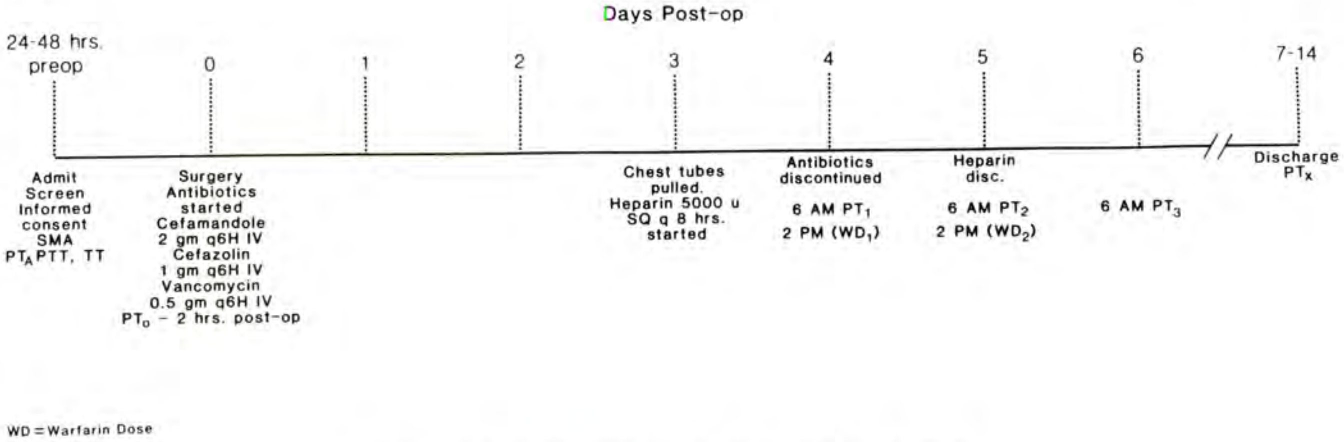

FIG. 1. The typical hospital course for a prosthetic valve patient.

Institutional Review Board and informed consent was obtained the day before surgery.

Preoperative exclusion criteria were: (1) PT 2 seconds greater than control, platelets $< 150{,}000$ cells/μL, PTT greater than normal, thromboplastin time (TT) 2 seconds greater than control; (2) a history of active liver disease; (3) a serum creatinine level of >2 mg/dL, BUN > 40 mg/dL; and (4) emergent surgery due to rapidly worsening heart failure or bacterial endocarditis.

Patients were excluded in the postoperative period if they: (1) had a serum creatinine level of >2 mg/dL, BUN > 40 mg/dL; (2) experienced prolonged cardiovascular instability requiring vasopressors, vasodilators, intravenous inotropes, and/or intra-aortic balloon pump for more than 48 hours after operation; and (3) had liver impairment or hepatitis.

One team of five cardiovascular surgeons following a uniform protocol performed all surgeries in a single hospital. Surgical data were obtained from the anesthesia record, cardiopulmonary bypass record, and the operative reports. All patients received identical anesthetic agents, including pancuronium, fentanyl, ketamine, enflurane, and diazepam. A St. Jude's medical cardiac valve prosthesis was used in all patients. Cardiac pulmonary bypass was accomplished using moderate systemic hypothermia (28 C) and cold potassium cardioplegia. Cefamandole, 2 g, cefazolin, 1 g, or vancomycin, 0.5 g, were administered intravenously as the prophylactic antibiotic before the chest incision and every 6 hours up to 24 hours after chest tube removal.

The typical hospital course of these patients including surgery and postoperative recovery is outlined in Figure 1. Warfarin was the only oral anticoagulant used and administered at 2:00 P.M. each day. The PT was measured: on admission 24–48 hours before operation (PT_A); after operation immediately on return to the intensive care unit (PT_O); at 6:00 A.M. the beginning day of warfarin therapy (PT_1); and daily throughout the hospital stay. Warfarin therapy and dosage selection was at the discretion of the attending cardiologist and adjusted with a PT goal of 1.5–2 times control. The initial warfarin dose was 10 mg in 67% of patients. A PT was also obtained daily for 2 or 3 consecutive days (PT_B) between PT_O and PT_1 in nine patients who received cefamandole, in nine patients who received cefazolin, and in 12 patients who received vancomycin. The PT per cent change (PT%C) was computed by $PT_1\%A - PT_3\%A / PT_1\%A \times 100$.

The PT was measured by the Quick method using a Dade Thromboplastin-C reagent and processed using an MLA Electra-700 automatic coagulation timer (American Scientific Products, McGaw Park, IL) with a coefficient of variation (CV) of 1.8% at normal control and 4% CV at high control. The percentage of prothrombin activity (PT%A) was obtained by converting the PT in seconds to percentage activity by means of a calibration curve obtained from the laboratory. This relationship between PT seconds and PT%A is nonlinear as seen in Figure 2.

Warfarin plasma concentrations were determined by a reverse-phase, high-performance liquid chromatography (HPLC). Warfarin and the internal standard, p-chloro-warfarin, were extracted from acidified, citrated plasma with cyclopentane. The organic layer was evaporated and the residue was reconstituted with 200 μL of mobile phase consisting of 57% acetonitrile/43% water, pH 3.0. An aliquot was injected onto a DuPont Zorbax® C column (E. I. duPont de Nemours and Co., Inc., Wilmington, DE) and the effluent was monitored at 280 nm with a Waters® 440 absorbance detector (Millipore, Waters Chromatography Division, Milford, MA). Concentrations were directly proportional to the absorbance, and as little as 0.1 μg/mL warfarin could be detected in 200 μL of plasma. The assay was linear from

0.1 to 10.0 μg/mL with an absolute recovery greater than 80%. Intra-day assay CV ranged from 2.2 to 11.1% over a concentration range from 0.1 to 10.0 μg/mL. Standards assayed over a 6-month period had CVs ranging from 0.5 to 14.5%.[8]

Patients were assigned to a New York Heart Association (NYHA) functional class using the standard published criteria.[9]

The ANOVA with the Neuman–Keuls multiple range test was used to compare the means of the three groups, and linear regression was used for statistical evaluation of the data. Unless otherwise stated, all data are reported as the mean ± SD. Statistical significance was designated at the $p \leq 0.05$ level.

Results

The demographic data describing the three groups as listed in Table 1 indicate the groups were well matched for sex and type of surgery. The patients who received cefamandole and cefazolin were significantly older than those receiving vancomycin. The NYHA classification of cardiovascular status was similar for the three groups, with the majority (70%) in Class III. Some of the more important parameters that were assessed and not found to be significantly different among the three groups are: (1) sex, (2) PT$_A$, (3) PT$_O$, (4) time on cardiopulmonary bypass, (5) length of surgery, (6) time of anesthesia, (7) total blood loss during and 24 hours after surgery, and (8) serum albumin level.

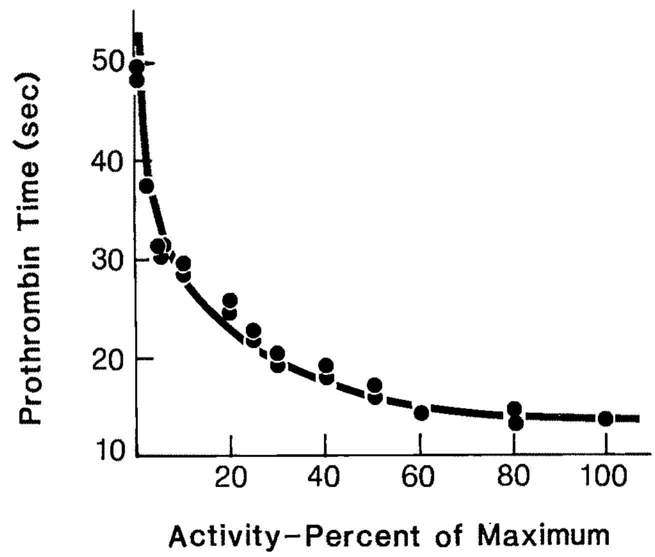

FIG. 2. Prothrombin percent activity: second relationship. The relationship between per cent activity and the prothrombin time in seconds is curve linear on a linear–linear scale.

Five patients received potentially interacting drugs in the postoperative period. They were cefamandole (2 patients: 1 quinidine, 1 cimetidine), cefazolin (1 patient: cimetidine), and vancomycin (2 patients: 1 quinidine and 1 cimetidine). Quinidine and cimetidine may potentiate the effects of warfarin.[10] Removing these patients from their respective groups did not alter any of the statistical values; therefore, they are included in all the reported results.

$PT_3 \geq 20$ seconds (N)	17	10	5

* PT_1 = baseline PT on 0600 the day warfarin is started.

† PT_3 = 16 hours after second warfarin dose.

$$‡\ PT\%C = \frac{PT_1\%A - PT_3\%A}{PT_1\%A} \times 100$$

§ WD_1 = warfarin dose, day one.

‖ WD_2 = warfarin dose, day two.

¶ Warfarin plasma levels obtained with PT_3.

# Cefamandole, cefazolin > vancomycin, $p < 0.05$.

** Cefamandole > cefazolin, vancomycin, $p < 0.01$.

The PT_1%A for the three groups was not significantly different ($p = 0.113$) (Table 2). PT_3%A was significantly lower for cefamandole and cefazolin, when compared with vancomycin, but not from one another. In contrast, the PT%C was significantly greater for cefamandole, compared with cefazolin and vancomycin, which were not significantly different. The first warfarin dose was ≥10 mg in 80% of patients receiving cefamandole, in 55% of patients receiving cefazolin, and in 85% of patients receiving vancomycin with the mean dose for each of the first two days and total dosage being similar. Warfarin plasma levels obtained with the PT_3 sample were not significantly different among the three groups. Cefamandole had a greater number of patients with PTs greater than both 20 and 30 seconds at PT_3 than the other two antibiotic groups.

The other identifiable difference between the three antibiotic groups was the relationship between the duration of postoperative prophylactic antibiotic therapy and the PT_1%A. Because the commencement of warfarin therapy was not controlled during this study, Table 3 lists the numbers of patients in each group who were receiving antibiotics concurrently when either PT_1, PT_2, or PT_3 was obtained. A linear regression using only those patients receiving antibiotics concurrent with the PT_1 sample compared the duration of antibiotics with the PT_1%A and indicated a moderate negative correlation for the cefamandole group ($R = -0.52$, $p = 0.05$) (Fig. 3), but not for cefazolin ($R = -0.16$, $p = 0.53$) or the vancomycin group ($R = -0.08$, $p = 0.82$). The mean duration of antibiotic therapy up to PT_1 was not significantly different among the three groups ($p = 0.12$).

TABLE 3. *The Number of Patients Receiving Concurrent Antibiotic Administration During the Time PT Samples Were Obtained and Average Duration of Antibiotic Therapy Until PT_1*

	Cefamandole N = 20	Cefazolin N = 20	Vancomycin N = 20
PT_1	15 (75)*	19 (95)	12 (60)
PT_2	14 (70)	11 (55)	8 (40)
PT_3	2 (10)	5 (25)	1 (5)
Therapy until PT_1 (days)†	4.6 ± 1.6	4.1 ± 0.8	3.8 ± 1.2

* N (% of total patients).

† Average number of days of antibiotic therapy until PT_1 obtained.

All of the PT_B%A values were greater than the patients' own PT_O%A. At least one of the PT_B%A values was equal or lower than the patients' PT_A%A in seven of nine patients (78%) who received cefamandole, in two of nine patients (22%) who received cefazolin, and in one of 12 patients (8%) who received vancomycin.

No bleeding episodes requiring transfusion were observed for the 60 patients. No apparent differences in outcome were associated with the three antibiotic groups and associated warfarin therapy.

Discussion

This prospective study reconfirms our previous retrospective report that patients receiving cefamandole, as a prophylactic antibiotic, had a greater hypoprothrombinemic response to warfarin than similar patients receiving vancomycin in the early postoperative period after prosthetic valve replacement. We reported previously that 14 of 44 patients (32%) receiving cefamandole and one of 16 patients (6%) receiving vancomycin had a $PT_3 > 32$ seconds, 16 hours after the second warfarin dose.[7] This is comparable to four of 20 (20%), 0 of 20, and 0 of 20 patients receiving cefamandole, cefazolin, and vancomycin, respectively, with a $PT_3 \geq 32$ seconds in the current study.

Although the PT%C supported a greater hypoprothrombinemia effect of cefamandole compared with cefazolin and vancomycin, we were surprised that the mean PT_3%A data were unable to differentiate statistically between cefamandole and cefazolin. This could be a result of too small of a sample size. The recent literature provides a possible explanation, but first we should review the three reported mechanisms of cephalosporin-induced hypoprothrombinemia.

The commonly cited mechanisms are[11]: (1) alteration of the bacterial bowel flora, with the suppression of vitamin K_1 production, (2) an inhibition of the carboxylation process necessary for the transformation of the procoagulant factors II, VII, IX, X to their active forms, and (3) the inhibition of vitamin K 2,3-epoxide reductase, which interferes with Vitamin K_1 activity.

The role of bowel flora in vitamin K production and its importance in maintaining a normal PT in humans is a subject of some dispute.[11] Most episodes of hypoprothrombinemia attributed to this mechanism have involved long-term, multiple antibiotic usage in seriously ill, malnourished, and potentially vitamin K-depleted patients or those with renal failure.[12] Our patients were not in renal failure; however, Blackburn et al. did report a 53% incidence of malnutrition in patients with a primary cardiac diagnosis. A subsample of 14 patients with valvular disease in NYHA Class III and IV were found to have a decreased weight/height index, skinfold thickness, and muscular circumference. Their patients' albumin levels, like ours, were generally within normal limits, but 10 of 14 patients tested negative for cell-mediated immunity.[13] We did not conduct a sophisticated nutrition assessment and cannot discount the possibility that an occult vitamin K deficiency existed, even with a normal PT_A before operation.

The pharmacologic basis for mechanisms 2 and 3 center on the MTT side chain found in not only cefamandole and several other cephalosporins (moxalactam, cefoperazone, cefotetan). Cephalosporins with the MTT side chain have been reported to cause hypoprothrombinemia more quickly and with greater frequency than non-MTT containing cephalosporins.[11] Lipsky reported that MTT inhibited gamma-carboxylation in a microsomal preparation prepared from rat livers.[14] Utolia and Suttie demonstrated that this inhibition was not due to the parent compound by reporting that cefamandole and structural analogs required much larger, and not clinically relevant, concentrations to produce 50% inhibition of the vitamin K-dependent carboxylase system.[15]

Vitamin K_1 2,3-epoxide reductase is found in the liver microsomes and reduces the vitamin K epoxide, formed from vitamin K_1 by carboxylase, back to the quinone or hydroquinone. Inhibition of vitamin K metabolism at the epoxide reductase step blocks the utilization of this vitamin. Bechtold et al. measured serum concentrations of vitamin K_1 2,3-epoxide, after giving 10 mg of vitamin K_1 intravenously in patients experiencing moxalactam- or cefamandole-induced hypoprothrombinemia. This metabolite is only measurable when vitamin K_1 is given in the presence of epoxide reductase inhibitors, such as coumarins or salicylates, and provides some inferential evidence that cefamandole has a coumarin-like action.[16]

None of the previous discussion would seem to support the possibility that cefazolin should have an additive hypoprothrombinemic effect with warfarin in our patient population. Kerremans et al. reported *in vitro* evidence that not only did MTT inhibit gamma-carboxylation but that MTD (2-methyl-1,3,4-thiadiazole-5-thiol), found in cefazolin, also had a similar effect.[17] They also demonstrated that the carboxylation inhibitory activity of both MTT and MTD was attenuated by methylation. Furthermore, MTD was a better substrate than MTT for both methylation enzymes: (1) thiopurine methyltransferase located in the kidney, and (2) thiomethyl transferase located in the liver. This could infer that MTD does not cause the same degree of hypoprothrombinemia because of rapid inactivation. However, MTD formation from cefazolin has not been demonstrated *in vivo.*[17]

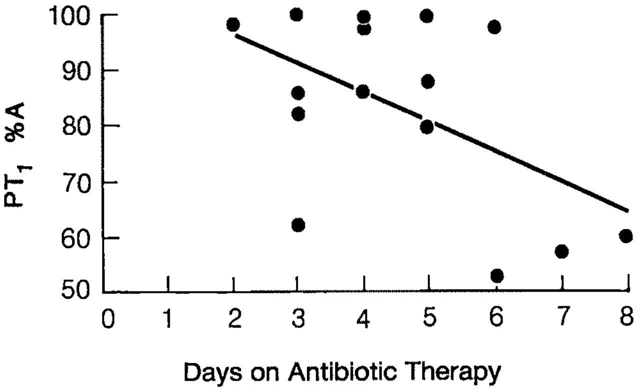

FIG. 3. The relationship between the duration of cefamandole administration and prothrombin per cent activity. The relationship between the double/double duration of prophylactic cefamandole therapy and the prothrombin time per cent activity on the morning that warfarin therapy was begun ($R = -0.52$, $p = 0.05$), indicating that as duration increased prothrombin activity declined.

Hypothermic cardiopulmonary bypass has influence on the entire clotting system. The vitamin K-dependent coagulation factors (II, VII, IX, X) have been reported to be depressed from 46% to 62% of preoperative values immediately after bypass.[18] This is consistent with our PT_O%A given in Table 1. Mori et al. measured the PT before operation and daily for 2 weeks after bypass surgery and reported that in only the first postoperative day PT, in seconds, was significantly greater than the preoperative PT. All PT values were within normal limits but the prophylactic antibiotic and its regimen were not specified.[19] A limited number of our patients in each group had two or three PT_B obtained and indicated a spontaneous recovery toward normal from the PT_O during the first 3–5 postoperative days. There is some hint that this return toward normal was inhibited in the cefamandole group by having more patients with a PT_B%A equal or less than their respective PT_A%A. In addition, there was a moderate correlation between an increasing duration of cefamandole therapy and decreased PT_1%A.

Although we did not attempt to quantitate the oral vitamin K intake of our patients after operation, the usual impression is that MTT-induced hypoprothrombinemia is quickly and easily reversed in a matter of hours by vitamin K administration.[11] This has not been universally true as Hooper et al.[5] and Fainstein et al.[20] reported. Lipsky provides experimental evidence that this MTT-induced hypoprothrombinemia may not be just a vitamin K inhibition problem because vitamin K_1 failed to reverse *in vitro* MTT inhibition of gamma-carboxylation after the reaction had started.[21] This may partially explain the low PT_1%A values that were noted in the cefamandole and cefazolin groups despite some oral food intake.

Yacobi et al. reported that 31 cardiovascular patients had total warfarin plasma levels of 0.4–3.27 μg/mL associated with a PT range of 15.6–29.8 seconds.[22] The warfarin plasma levels we obtained measured only the total racemic compound and were not at a steady state. Even so, they indicate that warfarin absorption took place, achieved similar concentrations, and are consistent with previous reported therapeutic concentrations in all three antibiotic groups.

The PT response to warfarin is influenced by many factors such as age, diet, congestive heart failure, or drug interactions to list a few. Sawyer et al. recently reported that age had a negative correlation with warfarin dosage requirements. This study included outpatients and a wider range of ages (19–91 years) than our patients.[23] The possible influence of the vancomycin group being 6–8 years younger on the PT response to warfarin in this setting is unknown. Yacobi et al. could find no rank order correlation between the average PT and average warfarin dose, total warfarin concentration, or free warfarin concentration.[22] The "normal" response to warfarin in the early postoperative phase in patients who had prosthetic valve replacement has not been rigorously documented to our knowledge; therefore, we cannot discount some other explanation for the observed differences among the three antibiotics. The consistent difference in PT response between cefamandole and vancomycin in this and our previous report, involving a total of 100 patients, supports a drug-induced effect.

The exact mechanism for the greater PT%C associated with the cefamandole group compared with cefazolin and vancomycin is unknown, but could possibly be due to the presence of MTT when the first warfarin doses were administered. The pharmacokinetics of MTT in this setting have not been reported and it is only recently that Aronoff et al. reported MTT disposition in a group of normal patients and in patients with anuric renal failure after a single intravenous dose of cefamandole. The patients with renal failure had a 10-fold increase in cefamandole half-life, and the MTT area under the curve was 50 times that seen in normals.[24] The importance of this is to the development of hypoprothrombinemia, or interaction with warfarin requires further study.

The possibility that the dosage regimens used for cefamandole and cefazolin were of unequal "PT suppression" potency cannot be discounted. We did not measure serum concentrations of either drug. Utolia and Suttie reported that cefamandole concentrations 10 times those observed after 2 g administered intravenously were needed to inhibit the vitamin K-dependent carboxylase system by 50%.[15] We were unable to find comparable data for cefazolin. Therefore, serum measurements of both parent compounds plus MTT and MTD would have to be done in an attempt to determine the relative "PT suppression" potency of these two cephalosporins.

Conclusion

This prospective study reconfirms our previous retrospective report that cefamandole can have an additive effect to warfarin in producing hypoprothrombinemia in the prosthetic heart valve patient. The study further provides evidence that cefazolin may have a similar, but intermediate, effect between cefamandole and vancomycin. Although none of our patients had an adverse reaction from this exaggerated hypoprothrombinemic response, we still recommend a baseline PT and caution before administering warfarin to patients receiving either cefamandole or cefazolin. The exact mechanism for this exaggerated hypoprothrombinemic response to warfarin after the administration of cefamandole or cefazolin is not completely understood but may be related to the MTT or MTD side chain and its influence on either gamma-carboxylation and/or vitamin K_1 2,3-epoxide reductase.

Lower torso ischemia leads to acute respiratory failure, an event associated with the accumulation of inflammatory cells in the lungs. This study tests whether ischemia-induced eicosanoid synthesis leads to polymorphonuclear leukocyte (PMN) accumulation in the lungs. Anesthetized rats ($N = 51$) were randomized into five groups: nonischemic sham rats ($N = 10$); the remaining four groups were rats made ischemic for 4 hours with bilateral thigh tourniquets treated just before tourniquet release with saline vehicle ($N = 17$): the thromboxane (Tx) synthase inhibitor OKY-046 (Ono Pharmaceutica, Osaka, Japan) 2 mg/kg intravenously every 2 hours ($N = 8$); the lipoxygenase inhibitor diethylcarbamazine (DEC) (Sigma, St. Louis, MO) 0.2 mg/kg/min intravenously ($N = 8$); the platelet-activating factor receptor antagonist SRI (Sandoz Inc., East Hanover, NJ) 63-072 3 mg/kg intravenously every 30 minutes ($N = 8$). Four hours after ischemia, plasma TxB_2 levels in the ischemic placebo-treated group was 3570 ± 695 pg/mL, compared with 495 ± 73 pg/mL in sham rats ($p < 0.001$). Lung microscopy showed foci of proteinaceous exudate in alveoli and 121 ± 10 PMN/20 high power fields (HPF) compared with 59 ± 9 PMN/20 HPF in the sham group ($p < 0.001$). One day after ischemia PMN accumulations remained elevated at 119 PMN/20 HPF. Pretreatment with OKY-046 led to reduced TxB_2 levels of 149 ± 17 pg/mL, normal lung histology, and 83 ± 13 PMN/20 HPF, a value similar to that of the sham group and lower than that of the placebo-treated group ($p < 0.05$). Treatment with DEC yielded TxB_2 levels of 1419 ± 492 pg/mL, which was lower than that of the placebo group ($p < 0.05$) but higher than that of the sham group ($p < 0.05$). Microscopy showed normal lungs with 79 ± 7 PMN/20 HPF lower than the placebo group ($p < 0.05$). SRI 63-072 did not inhibit Tx synthesis or leukosequestration in the lungs. Platelet counts decreased in all groups relative to sham animals ($p < 0.05$). The results indicate that Tx synthesis induced by ischemia moderates PMN accumulations in the lungs. Inhibition of lipoxygenase is believed to prevent PMN accumulations both by limiting leukotriene-induced Tx synthesis as well as by limiting production of chemoattractants.

LOWER TORSO ISCHEMIA stimulates the release of a circulating agent(s), which leads to the accumulation of blood cells including polymorphonuclear leukocytes (PMN) in the lungs.[1,2] Neutrophil entrapment is considered to be the final event resulting in the local release of toxic agents and acute respiratory failure.[3]

Previous studies of ischemia have concluded that pulmonary injury occurs when blood cell microemboli are mechanically sieved by the lungs.[4] Since synthesis of the proaggregator and chemoattractant TxA_2 is stimulated by ischemia,[5] the current study was designed to test its role in blood cells, particularly neutrophil accumulations in the lungs. Further, the role of two other chemoattractants and activators of neutrophils, the leukotrienes (LT) and platelet-activating factor (PAF),[6-8] were included in the study to test their roles in pulmonary leukosequestration.

Methods

Fifty-seven male Sprague-Dawley rats (Charles River Breeding Laboratories, Wilmington, MA), weighing an average of 500 g, were anesthetized with 60 mg/kg of pentobarbital sodium administered by intraperitoneal injection. A jugular venous catheter was inserted for supplementary doses of anesthesia as well as fluid and drug administration. The volume of fluid given in all experiments was 2 mL/kg/h.

The animals were divided into five groups. In all animals, except the sham controls ($N = 10$), arterial tourniquets were applied to both thighs after a 2-minute elevation of the hind limbs to minimize the amount of retained blood. The animals were then placed prone, and after 4 hours the tourniquets were removed. Thirty minutes before tourniquet release, animals were randomized to receive: saline vehicle ($N = 23$); the thromboxane (Tx) synthase inhibitor OKY-046 (Ono Pharmaceutica, Osaka, Japan), 2 mg/kg by intravenous bolus, repeated every 2 hours ($N = 8$); the lypoxygenase

inhibitor diethylcarbamazine (DEC)[9] (Sigma, St. Louis, MO), 0.2 mg/kg/min in a continuous intravenous infusion (N = 8); the platelet-activating factor (PAF) receptor antagonist SRI 63-072[10] (Sandoz Inc., East Hanover, NJ) in repeated intravenous boluses of 3 mg/kg every 30 minutes (N = 8). Treatment in all animals was continued for 4.5 hours when the experiment was ended.

After 4 hours of reperfusion, a midline laparotomy was performed and 5 mL of blood withdrawn from the inferior vena cava in syringes containing ethylene diamine tetracetic acid and aspirin. Platelets were counted by means of phase microscopy. The blood was then centrifuged at 1500 × g at 4 C for 20 minutes, the plasma separated and stored at −20 C until assayed. Plasma TxB_2 and 6-keto-$PGF_{1\alpha}$ were measured by radioimmunoassay.[11-13]

The rats were killed with intravenous potassium chloride, and the lungs harvested for light microscopy. This was done *via* a midsternotomy. Through a tracheostomy, gluteraldehyde was introduced into the lungs and kept under a constant hydrostatic pressure equivalent to a 20-cm column of water for 20 minutes. The trachea was then ligated, and the lungs removed and bathed in gluteraldehyde for 24 hours. Sections were taken from identical lung regions and were stained with hematoxylin and eosin. Leukocytes were counted in 20 high power fields (HPF). Sham control animals were studied (N = 10) where all procedures were done except the hind limbs were not made ischemic. Four animals of the sham group and three of the placebo-treated group were used to determine wet-to-dry lung weight ratios of the bloodless lung at the conclusion of the experiment, that is, after 4 hours of hind limb ischemia and 4 hours of reperfusion. Lastly, plasma TxB_2 levels, lung weights, and PMN entrapment were assayed in placebo-treated rats 24 hours (N = 3) and 48 hours (N = 3) after ischemia.

Results are presented as the mean ± SE. Significance between means was tested by an analysis of variance and nonpaired t-test. Significance was accepted if $p < 0.05$.

Animals used in this study were maintained in accordance with the guidelines of the Committee of Animals of the Harvard Medical School and those prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animal Resources, National Research Council (DHEW publication no. [NIH] 78-23, revised 1978).

Results

Four hours of reperfusion after a 4-hour period of hind limb ischemia resulted in a rise of plasma TxB_2 in the placebo-treated animals to 3579 ± 695 pg/mL, compared with 495 ± 73 pg/mL in the nonischemic sham group ($p < 0.001$) (Fig. 1). There was also a rise in 6-keto-$PGF_{1\alpha}$ to 285 ± 50 pg/mL compared with sham treatment values of 156 ± 50 pg/mL ($p < 0.05$) (Fig. 2).

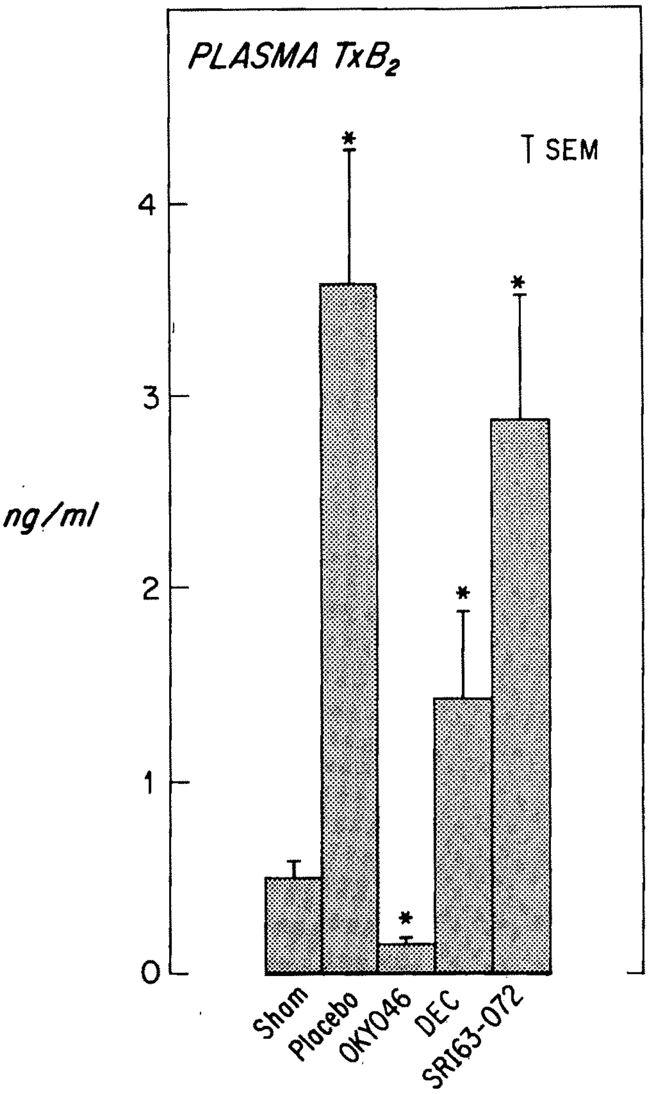

FIG. 1. Four hours of reperfusion after bilateral hind limb ischemia led to a rise in plasma TxB_2 levels compared with those of sham animals. OKY-046 prevented this phenomenon, whereas DEC modified it. The PAF antagonist, SRI 63-072, was without effect. Asterisks refer to significant differences between the sham group and other groups.

Microscopic examination of the lungs of sham animals showed normal histologic features (Fig. 3), whereas placebo-treated ischemic animals demonstrated accumulations of PMNs in the capillary beds throughout the lung parenchyma (Fig. 4). Most neutrophils were contained within vessels, but foci of inflammatory cells and proteinaceous exudate within alveolar air spaces were also present. The accumulation of PMNs in the lungs was in excess of what could be attributed to local differ-

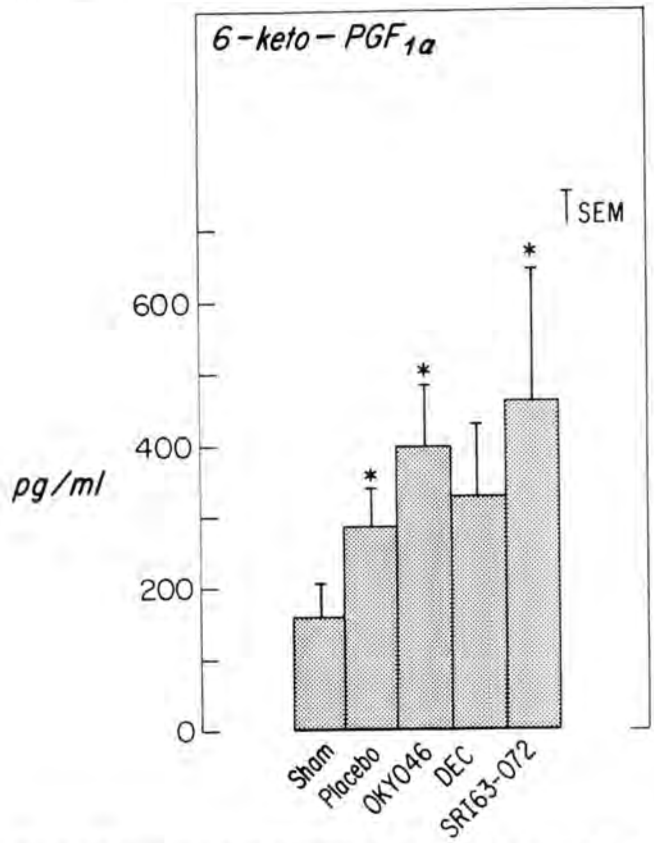

FIG. 2. After ischemia there was an increase in plasma 6-keto-$PGF_{1\alpha}$ in all groups compared with the sham group, although the rise in the DEC group was not significant. Asterisks refer to significant differences between the sham group and other groups.

ences in blood volume or vascular congestion. Quantitative counts of PMN in the lungs were 121 ± 10 PMN/20 HPF, higher than the sham group value of 59 ± 9 PMN/20 HPF ($p < 0.001$) (Fig. 5). Wet-to-dry weight ratios of the lungs in placebo-treated and sham groups were 4.97 ± 0.24 and 4.89 ± 0.05, respectively.

Pretreatment with OKY-046 blocked ischemia induced TxB_2 synthesis. After 4 hours of reperfusion, TxB_2 levels were 149 ± 17 pg/mL, lower than the sham group ($p < 0.001$). Few abnormalities were noted on microscopy. Accumulation of neutrophils was 83 ± 13 PMN/20 HPF, similar to that of the sham group and reduced compared with that of placebo-treated animals ($p < 0.05$) (Fig. 5). In the DEC-treated group, TxB_2 levels were 1419 ± 492 pg/mL, a value higher than that of sham animals ($p < 0.05$) but lower than that of the placebo-treated group ($p < 0.05$) (Fig. 1). Histologic features of the lungs were virtually normal, and leukocyte count in the lungs was 79 ± 7 PMN/20 HPF (Fig. 5), lower than that of the placebo-treated group ($p < 0.05$). The PAF antagonist, SRI 63-072, had no significant effect on TxB_2 levels, 2912 ± 635 pg/mL, nor on leukosequestration in the lungs, 110 ± 26 PMN/20 HPF, both measurements being higher than levels in sham animals and similar to levels in placebo-treated animals.

Platelet counts decreased significantly in all four ischemic groups compared with that of sham animals ($p < 0.05$) (Fig. 6). Platelet aggregates were not seen in histologic sections.

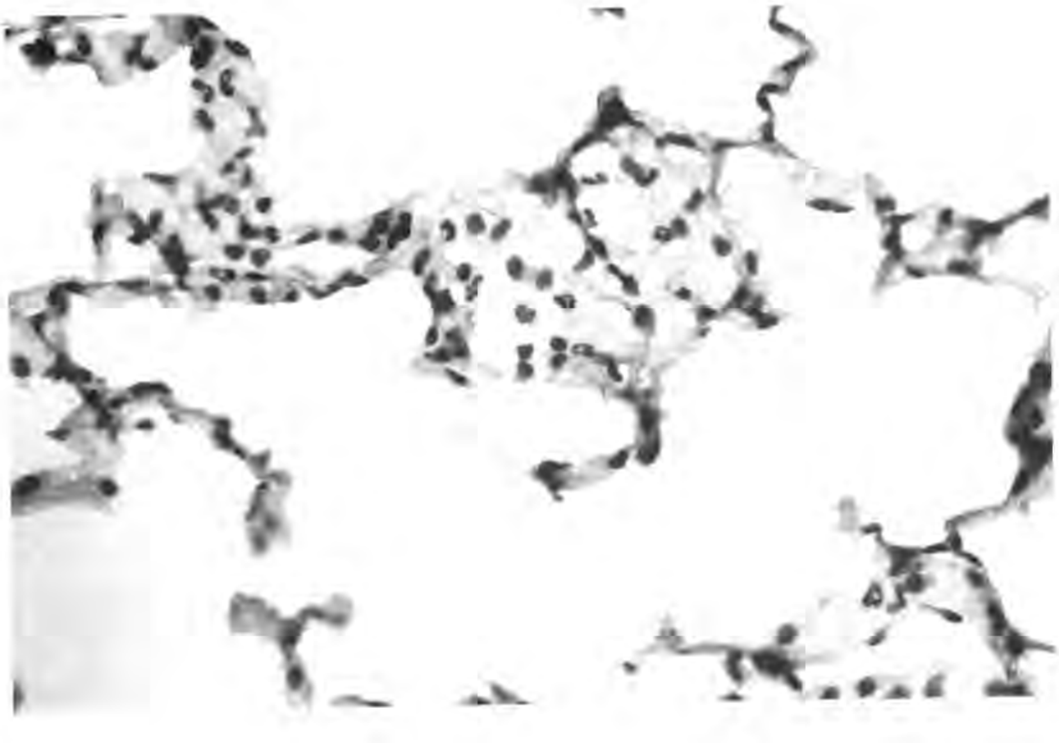

FIG. 3. Histologic specimens of the lungs in placebo-treated animals showed accumulations of PMNs in the capillary bed, mostly within vessels. Occasionally, foci of inflammatory cells and proteinaceous exudate were present within alveolar air spaces as seen in the central portion of the figure.

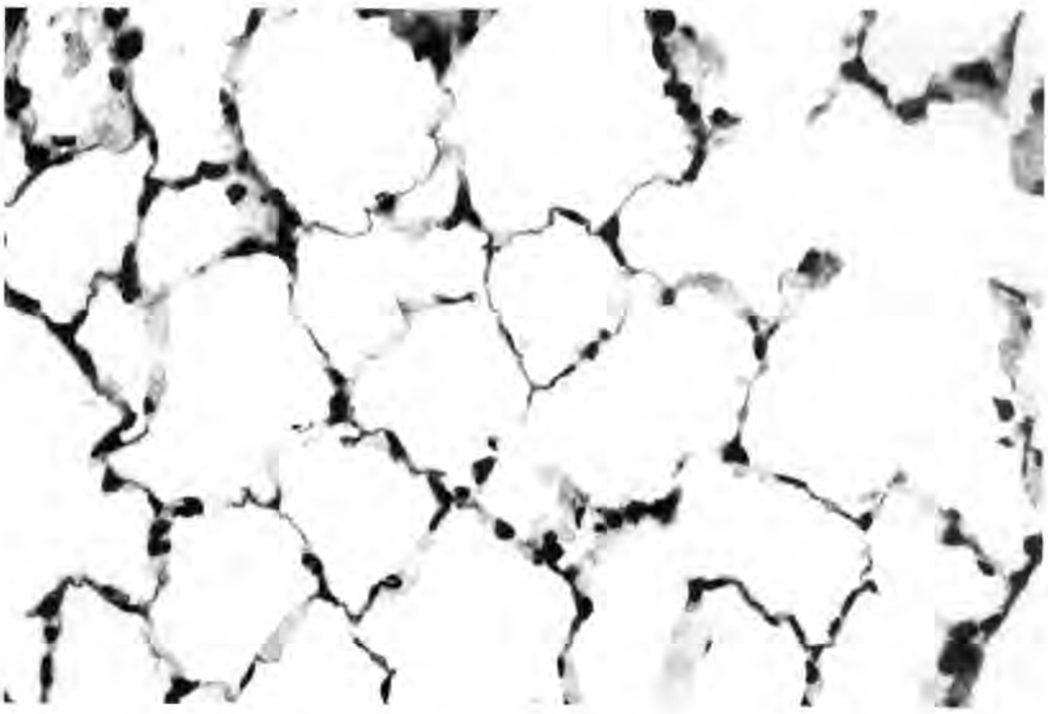

FIG. 4. The histologic features of lungs of sham animals were normal.

Placebo-treated animals that were studied 24 hours after release of the thigh tourniquets had normal TxB_2 levels of 436 ± 105 pg/mL but lung leukocyte counts were still high at 119 ± 1 PMN/20 HPF. After 48 hours, TxB_2 levels were 763 ± 118 pg/mL and lung leukocyte counts were 94 ± 6 PMN/20 HPF.

Discussion

Reperfusion after a 4-hour ischemic stimulus led to a prominent rise in plasma TxB_2, which returned to baseline after 24 hours. Similar findings have been noted in dogs after application of a thigh tourniquet and in humans after abdominal aortic cross-clamping during aneurysm surgery.[5,14] Associated with this rise in TxB_2 was an accumulation of leukocytes in the lungs (Fig. 5) that cleared slowly, over the next 2 days. Although there was no increase in the wet-to-dry weight ratio 4 hours after ischemia when PMN accumulations were prominent, there was histologic evidence of microvascular injury manifest by focal proteinaceous exudate into alveolar air spaces (Fig. 3). Previous observations of the pulmonary consequences of lower torso ischemia have documented blood cell accumulations in the lungs, believed to be due to embolization of microaggregates from the ischemic legs.[1,2,4] That platelet counts were noted to fall during neutrophil sequestration in the lungs (Fig. 6) is consistent with the formation and embolization of platelet microemboli. However, histologic observations make this unlikely. Platelet aggregates were not noted by lung microscopy in animals who had PMN accumulations (Fig. 3). Secondly, pharmacologic inhibition of Tx and LT was successful, at least in part, in preventing the PMN accumulations in the lungs but not the decline in circulating platelet numbers (Figs. 5 and 6). It is unlikely that the proaggregators being inhibited, that is TxA_2, would selectively aggregate PMNs and not platelets.

That mechanical filtration of PMN aggregates by the lungs is unlikely makes plausible the thesis that agents such as TxA_2 and LTB_4 lead to pulmonary endothelial–neutrophil interactions.[15] Adherence of PMN to pulmonary endothelium is a necessary initial step. It is possible that LTB_4 acts principally on endothelium.[16] LTB_4-stimulated Tx synthesis by endothelium, an event recently described,[17] may be a critical intermediary step. Thus, LTB_4 when applied to abraided skin or when injected subcutaneously will lead to the local generation of Tx and PMN accumulations, events that can be prevented with Tx synthase antagonists.[18] In other settings where Tx synthesis is stimulated, such as in experimental acid aspiration, PMN accumulations in the lungs are noted.[19] This can be limited by inhibition of Tx synthesis. The precise mechanism of TxA_2 action in these settings is unknown but is believed to involve endothelial–PMN adherence.

It is also theorized that thromboxane may act directly on actin filaments in endothelium in a manner similar

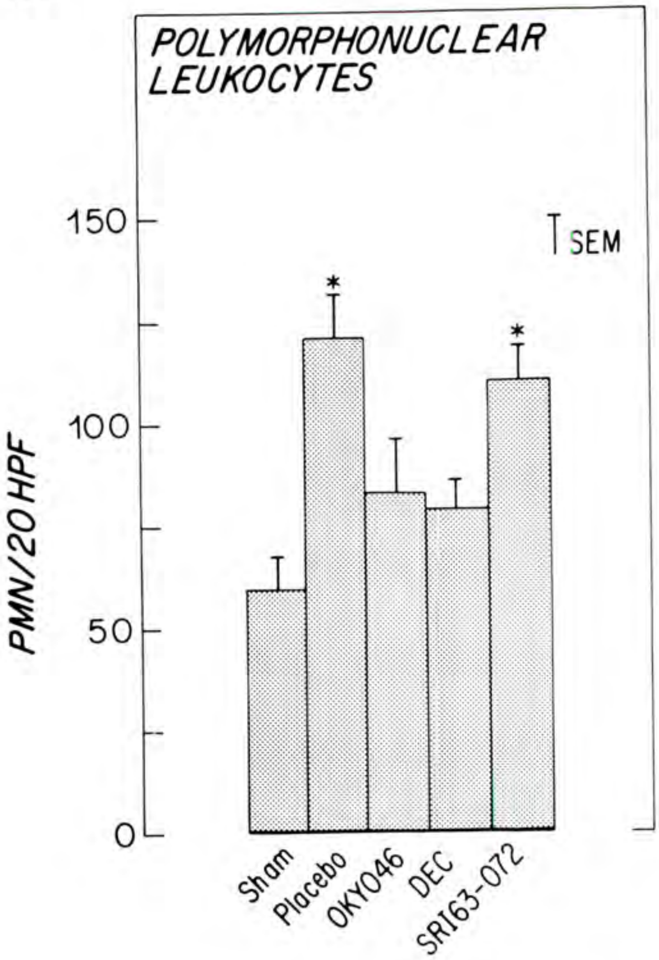

FIG. 5. Leukocyte entrapment was greater in placebo-treated animals than in the sham group. Pretreatment with OKY-046 and DEC significantly reduced pulmonary leukosequestration. Asterisks refer to significant differences between sham-treated animals and other groups.

to vasoactive amines to encourage PMN movement out of the microvasculature by diapedesis.[20] Actin filaments are believed to be important determinants of the size of intercellular clefts between endothelial cells. The opening of these tight junctions occurs when the actin cables are disassembled by agents such as histamine, LTB_4, and TxA_2.[21] This leads to increased permeability to macromolecules as well as to increased PMN diapedesis.[20,22]

The observation that treatment with DEC leads to a lowering of TxB_2 levels may be due to inhibition of LT and LT-induced generation of Tx.[17] The salutory effect of DEC on PMN accumulations may be due both to this reduction in TxA_2 as well as to a decrease in synthesis of the chemoattractant LTB_4. Both eicosanoids may contribute to leukosequestration by moderating the size of gap junctions as well as PMN–endothelial interactions.

The inability of the PAF antagonist SRI 63-072 to alter PMN accumulations was a surprise. We interpret the results to indicate that PAF is not released as a consequence of ischemia. In further support of this thesis, had PAF been released, circulating blood cells should have been stimulated to synthesize TxA_2.[23] Inhibition of PAF should then have led to a fall in plasma TxB_2, which did not occur.

Other agents, particularly the complement fragment C5a, are not likely to mediate ischemia-induced leukosequestration in the lungs. In a previous study, Tx inhibitors could not prevent PMN accumulations resulting from the intravenous injection of zymosan-activated plasma, a source of C5a. The vasodilating, antiaggregating prostaglandins (PG), such as PG_2, are also not likely to be involved. Levels of 6-keto-$PGF_{1\alpha}$ did not predict PMN accumulations nor did the PG/Tx ratio.

In summary, these results indicate that limb ischemia leads to Tx synthesis and PMN accumulations in the lungs, events that appear to be causally related.

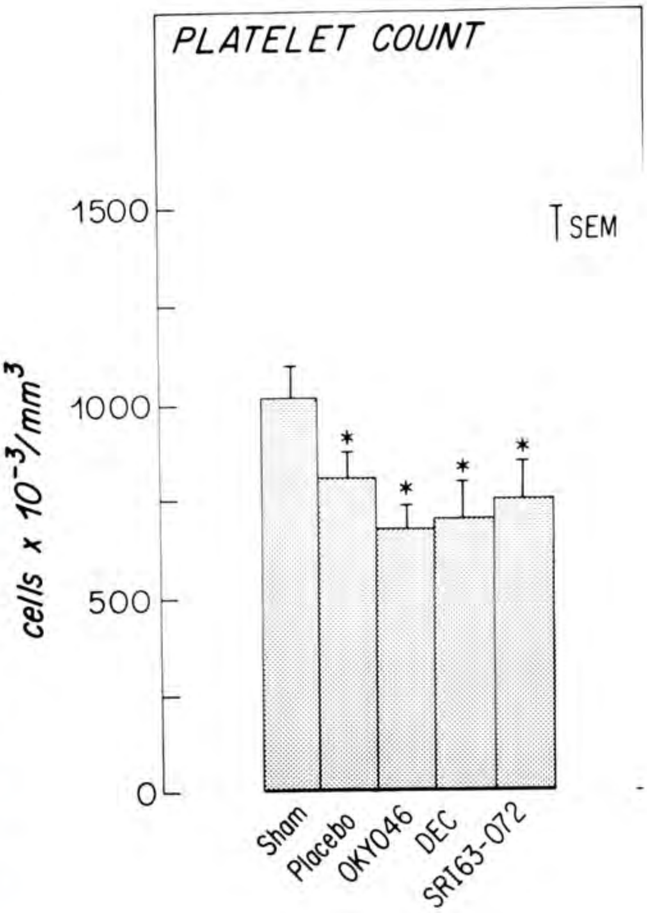

FIG. 6. Platelet counts fell in all ischemic groups. Asterisks refer t significant differences between the sham group and other groups.

Reoperation for Femoral Anastomotic False Aneurysm

A 15-year Experience

LUCA DI MARZO, M.D., ERIK L. STRANDNESS, M.D., RICHARD D. SCHULTZ, M.D., and RICHARD J. FELDHAUS, M.D.

From the Department of Surgery, Creighton University, Omaha, Nebraska

An experience on the surgical treatment of anastomotic false aneurysms during the last 15 years was reviewed. Fifty-nine were femoral anastomoses complicated by false aneurysm appearance requiring surgical excision. They represented 2.9% of all femoral anastomoses performed, whereas they represented 3.3% when considering reconstruction in which the femoral artery was the distal anastomosis. Reconstructions with distal anastomosis performed on the femoral artery were primarily involved (58 of 59), whereas grafts with "take off" from the femoral artery were rarely affected ($p < 0.05$). A higher incidence of false aneurysm formation was demonstrated in hypertensive patients ($p < 0.05$) as well as those who previously had femoral thromboendarterectomy ($p < 0.01$). Infection was considered a causative factor even if it developed before (6–14 months) false aneurysm appearance. When a false aneurysm was resected, the best hemodynamic reconstruction, to avoid recurrence, was considered a bypass with distal anastomosis performed end-to-end on the femoral artery ($p < 0.05$). The surgical treatment of choice was false aneurysm resection and graft interposition. However, a reanastomosis in the presence of small false aneurysms, when technically possible, has been successfully performed. Both treatments allowed good long-term results.

THE INTRODUCTION OF vascular grafts almost 30 years ago helped surgeons to solve many important vascular problems. Efforts since that time have been made to improve the quality of graft materials and their results. Better prostheses have been developed since that time with great improvement in the results. Nevertheless, graft implantation is still complicated by two major problems: the occurrence of anastomotic false aneurysms and infection. The first complication is common in the groin and currently constitutes an unsolved puzzle. Much work has been done to focus on the major factors influencing this vascular complication. The first imputed was the type of suture used to complete the anastomosis.[1-3] However, femoral false aneurysms continue to occur despite the abandonment of silk and braided Dacron as suture materials.[4,5] Infection, hypertension, tension of a graft, local thromboendarterectomy, and turbulance at the anastomotic site have also been considered as factors in many qualified reports.[4,6] However, it has not been clearly demonstrated that all of these factors are present more frequently in patients in whom false aneurysms developed than in patients in whom they do not. To clarify some of these etiologic factors, we present the experience of our group during the last 15 years.

Materials and Results

From 1971 through 1985, we have treated, by means of vascular reconstruction, a total of 2053 femoral sites in 1169 cases. The type of reconstruction performed is reported in Table 1. Sixty-six were femoral anastomoses complicated by an anastomotic aneurysm that required surgical excision (>3 cm): 59 (2.9%) were anastomotic false aneurysms, whereas the other seven were true aneurysms and were, therefore, excluded from this study. Thirty of the affected patients (24 men and 6 women) had a mean age of 66.4 years (SD ± 8.2), median age was 66 years. Forty-eight femoral sites were involved, and 11 were recurrent. Eighteen patients were bilaterally affected. Associated pathologic conditions are reported in Table 2.

All patients had extensive vascular disease with 80% having had a minimum of three vascular procedures (mean: 5.4). The diagnosis was always "clinical" (Fig. 1A). Angiography was limited to cases in which distal obstructive lesions or multiple false aneurysms were suspected (Fig. 2). All false aneurysms developed at the

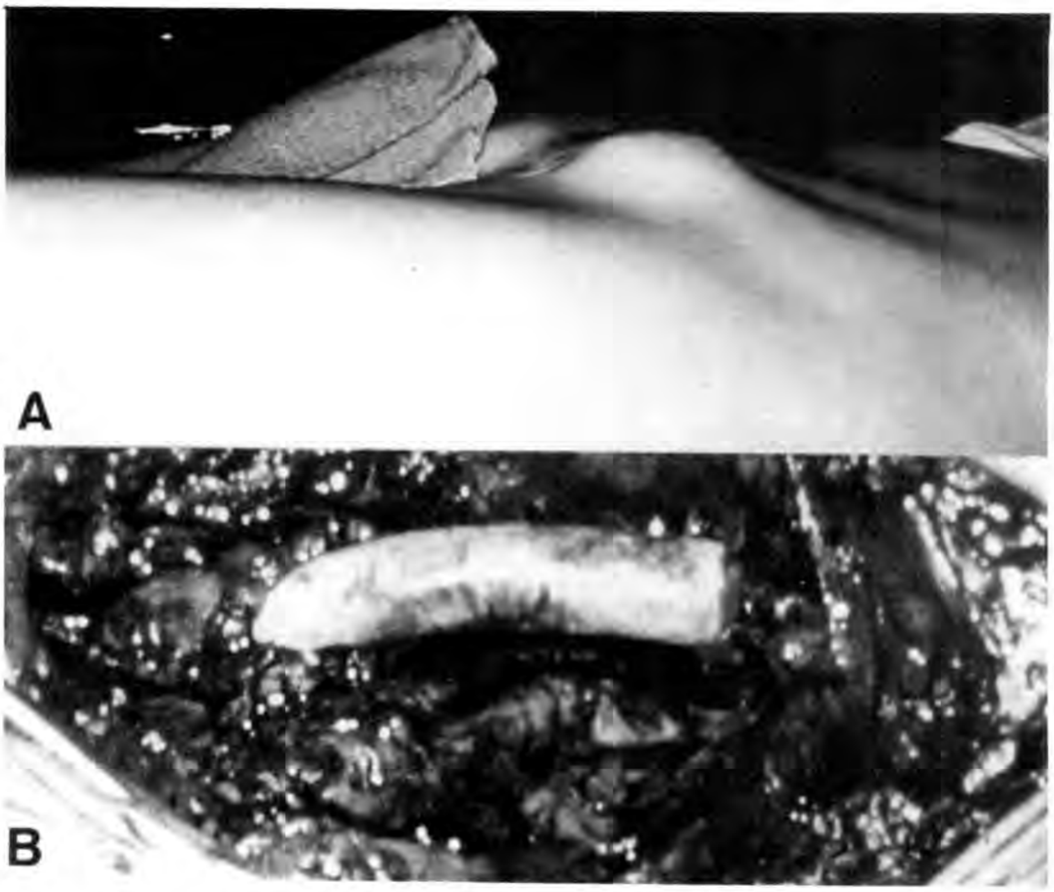
anastomosis between an aorto-, thoraco-, or femorofemoral graft and the femoral artery (distal anastomosis) except one, which appeared at the anastomosis between a femoropopliteal bypass and one limb of the previous aortofemoral reconstruction (proximal anastomosis). Thirteen patients were previously operated on for an abdominal aortic aneurysm and had 26 femoral false aneurysms (4 recurrences) develop. Seventeen patients were operated on for obstructive disease and had 33 false aneurysms (7 recurrences) develop. The surgical procedure consisted of an aneurysmectomy and graft reanastomosis in 14 (23.7%) patients. Although a local graft interposition was performed in 43 (72.9%) patients, in two (3.4%) patients, the entire aortofemoral reconstruction had been replaced due to a concommitant false aneurysm at the aortic site. The distal anastomosis of this reconstruction was performed end-to-end in 31 (52.5%) patients (Fig. 1B) and end-to-side in 11 (18.7%) patients. In one (1.7%) patient, we could not precisely indicate the type of distal anastomosis (Fig. 3). The sutures used to perform the anastomosis complicated by false aneurysm formation are shown in Table 3. Reoperation for false aneurysm was performed after a mean of 58.4 months (SD ± 28.7) from the previous vascular procedure. Recurrence of false aneurysm appeared after a mean of 30.1 months (SD ± 25.8) after the first repair.



FIGS. 1A and 1B. *A.* Patient affected by an anastomotic femoral false aneurysm. *B.* Intraoperative image of the PTFE graft used for repair. Both anastomoses were performed end-to-end.

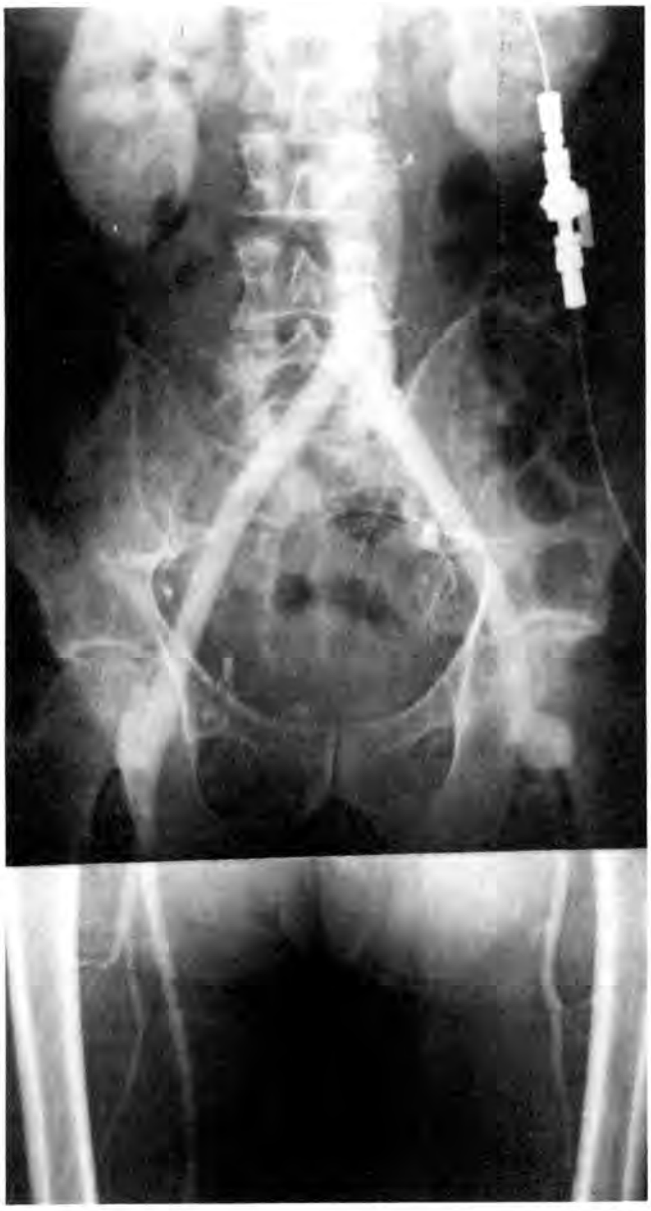


FIG. 2. Angiography of patient affected by an anastomotic femoral false aneurysm. Occlusion of left superficial femoral artery is shown, with complaints of related symptoms.

A previous femoral thromboendarterectomy was performed on a total of 26 (44.2%) patients. This procedure was primarily performed in patients treated for occlusive disease (18 of 33), whereas in abdominal aneurysms it was more infrequent (8 of 26).

Infection was considered a factor in seven cases; however, only two cases presented with a clinical infection and positive culture at the time of false aneurysm repair; whereas in five cases infection had been present before the repair (6–14 months). Cultures were always obtained and showed a negative result in all false aneurysms, except in the two cases with clear clinical infection.

Antibiotics were routinely used for 5–7 days after surgery.

The follow-up results showed an incidence of recurrence in patients treated by simple reanastomosis similar to the group treated by graft interposition: 21.4% and

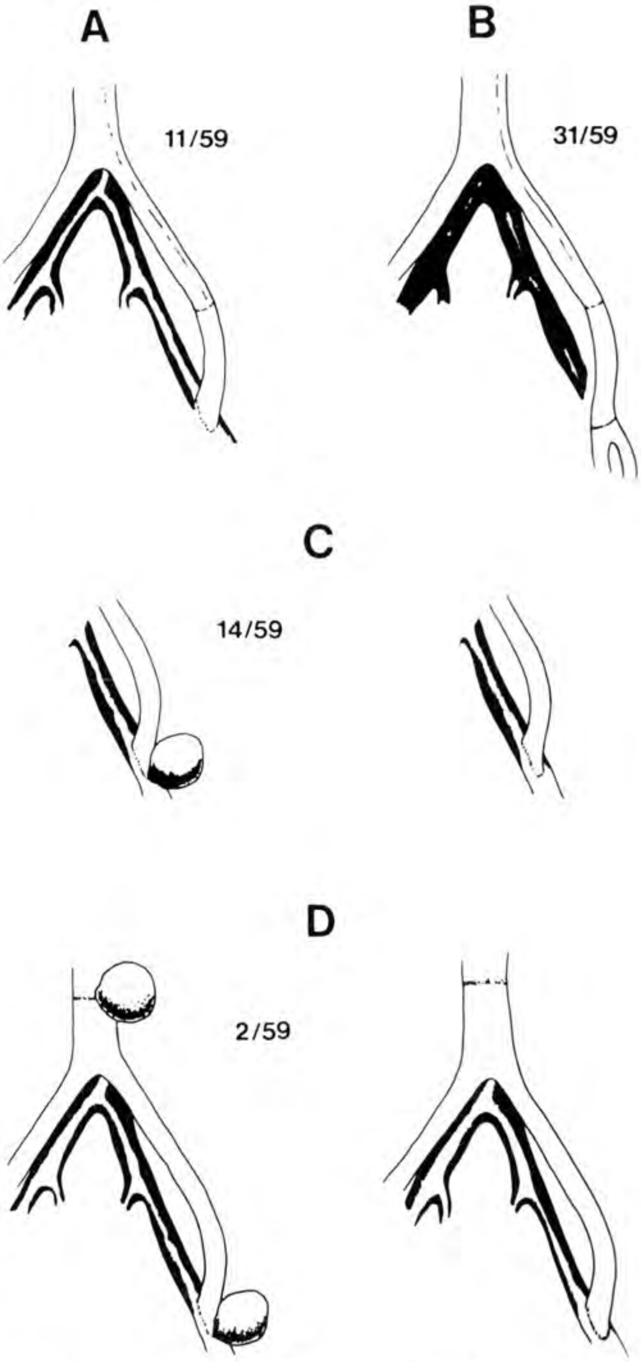

FIG. 3. Surgical procedures. One case treated by graft interposition has not been included because we could not clarify the type of distal anastomosis performed. Another case involved a venous femoropopliteal artery bypass and has been included in Group A. The treatment consisted of resecting the distal portion of the aortofemoral graft with graft (PTFE) interposition (end-to-end) and reanastomosis of the vein femoropopliteal bypass to this new graft.

17.5%, respectively (NS). In both groups, long-term results were successful (Table 4).

Discussion

Several different factors became evident concerning anastomotic false aneurysm. The femoral site is surely more affected than others. From the statistical analysis of our data, we can easily confirm that femoral false aneurysm is a complication of reconstruction with distal anastomosis performed on the femoral artery. False aneurysm development is rarely a problem when the femoral anastomosis represents the proximal part of the reconstructive procedure, 1:58 ($p < 0.05$). The etiology of this complication is multifactorial. The incident percentage has been reported to range between 2 and 5% in different reports.[1-10] In our series, the incidence was 2.9%, but if we consider only those reconstructions with distal anastomoses performed on the femoral artery, it increases to 3.3%. Great emphasis was given to the type of prosthesis and suture used to perform the original reconstruction. Undoubtedly, these are factors that may influence the development of false aneurysms. Cutler and Dunphy[11] demonstrated fragmentation of silk fibers and removal of fragments by phagocytes years ago. However, the great progress that has been done to improve the quality of suture and graft material has been widely reported as a cause of reduction in false aneurysm formation due to suture destruction or graft dilation. In the past, these two factors were reported with more emphasis than now.[8,9] To reinforce this hypothesis, Dennis et al.[4] emphasized how, in more recent reports, the time between the original operation and the false aneurysm appearance is longer (6.2 years) than in the past. This latter data are confirmed in our series (58.4 months); however, in our opinion, due to the long mean time of appearance of this complication, a definitive opinion on these factors can be given only after certain years because of the relatively recent introduction of monofilament sutures (1982 in our series).

Progressive arteriosclerotic deterioration of the femoral artery played a great role. Therefore, the quality of the host arterial wall is extremely important to preserve the anastomosis. Local thromboendarterectomy at this site with related weakening of the arterial wall and subsequent false aneurysm formation has already been described.[1,7,10] In our patients, this hypothesis was proved and was extremely important if we consider separately the patients operated on for aneurysm and for obstructive disease. The number of previous thromboendarterectomies in this last group was significantly higher compared with the number of thromboendarterectomies performed in our series during similar vascular reconstruction of the femoral artery not complicated by femoral false aneurysm (34.1%) ($p < 0.01$).

In our series, a clear-cut clinical infection with positive cultures at the site of false aneurysm repair was rarely present (2 cases/1 patient). These two cases were successfully treated by means of excision of the infected aortofemoral graft with saphenous vein reconstruction to each femoral area with a proximal and distal anastomosis as far distal as possible from the infected area. Antibiotics were used for 15 days after surgery, and the patient had no recurrence of infection (follow-up: 53 months).

Nevertheless, infection was considered a factor in seven (11.9%) of our cases. In five cases, false aneurysm developed 6–14 months after a graft infection (Szilagyi, grade 3). These five cases were treated by means of complete or partial excision of the infected graft and new vascular reconstruction. False aneurysm of this reconstruction site was considered to be related to a previous infection due to the same localization and relatively short time of developing, even though cultures were always negative. In Table 5 we present the removed infected grafts, their culture, and the new reconstruction complicated later by false aneurysm appearance and its follow-up. In our opinion, infection can be considered

TABLE 4. *Follow-up (Mean: 42.1 months)*

	No. of Patients (%)

Aorto-left femoral	*S. epidermidis*	Left stump to Left femoral	6	Infection recurrence; amputation and death at 30 months

an important but infrequent risk factor in the development of false aneurysm, which deserves long-term follow-up study.

In our series, hypertension was present in a significantly higher range (63.3%) than in the atherosclerotic population ($p < 0.05$) and can, therefore, be considered a risk factor.

Among the mechanical factors, we believe that the high difference of compliance between the prosthesis and the femoral artery is surely an important cause of stress of the anastomotic site. In a previous study,[12] our senior author (R.D.S.) demonstrated that the difference in resilience of diseased femoral arteries and prosthetic material can be 15 times superior. Moreover, the turbulence at the anastomotic site caused by the end-to-side anastomosis can submit the host artery to relatively high stress that easily can be related to the false aneurysm formation.

In our opinion, end-to-end anastomosis, if possible, should always be performed for a false aneurysm repair to minimize the turbulence caused by the end-to-side anastomosis and, therefore, avoid a recurrence. In our series, the false aneurysm recurrences appear in a higher incidence, 3:1, ($p < 0.05$) after an end-to-side reconstruction or reanastomosis compared with the end-to-end anastomosis. To minimize turbulent effects at the anastomotic site, Szilagyi et al.[6] suggested to perform the end-to-side anastomosis with a very small angle (30°). This helpful criteria should always be followed for aortofemoral reconstruction, but only as a second choice to repair a false aneurysm, when an end-to-end anastomosis is not possible.

Resection of false aneurysm and reconstruction with graft interposition provides good long-term results. Simple reanastomosis can also be performed with success in small false aneurysms and/or when technically possible. If the false aneurysm is infected, the graft should be removed and another vascular reconstruction performed as far distant as possible from the infected site. When a false aneurysm also involves the aortic site, a complete removal of the aortofemoral graft is the treatment of choice. Reviewing our 59 cases during the past 15 years, we can make the following conclusions: (1) femoral false aneurysm formation is an important, although infrequent, complication of arterial reconstructions with distal anastomosis on the femoral artery; (2) local thromboendarterectomy should be avoided at the femoral site when possible because it represents a factor of false aneurysm formation; (3) end-to-end anastomosis at the femoral site reduces the risk of false aneurysm development due to its better hemodynamics; (4) infection is a causative factor even if it develops before (6–14 months) the false aneurysm appearance; and (5) treatment of choice is a graft interposition, but also a reanastomosis can be successfully performed. Both treatments allow good long-term results.

ch 100 ml contains ranitidine 50 mg (as the hydrochlo
dium chloride 450 mg; and citric acid 30 mg and dibasic
dium phosphate 180 mg as buffers in water for injection
80 mOsm/liter (approx.); pH 6.7 to 7.3. Additives should
ot be made to this solution. Usual Adult Dose: See
ckage insert. Caution: Federal law prohibits dispensing
without prescription. Use only if solution is clear and con
tainer is undamaged. Must not be used in series connectio
98-1932-2/R-2 592802
Manufactured for Glaxo Inc.,
Research Triangle Park, NC 27709
by Abbott Laboratories, North Chicago, IL 6

Convenient

☐ Ready to use–no mixing needed
☐ Premixed 100-ml bag, containing 50 mg ranitidine (as the hydrochloride)
☐ No need to refrigerate
☐ Stores for up to 18 months

Cost effective

☐ Saves pharmacy and nursing time

Raises gastric pH acid in critical care patients for up to 8 hours*

No significant drug interactions with the hepatic P-450 enzyme system at recommended doses

☐ No clinically significant drug interactions between ranitidine and theophylline, phenytoin, or warfarin

Zantac® Injection Premixed

ranitidine HCl/Glaxo

New premixed 100-ml bag containing 50 mg ranitidine HCl

*Some patients may require q6h dosing.
See next page for brief summary of Product Information.

Glaxo/ROCHE

ZANTAC® Injection
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.

INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.

CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.

PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.

2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.

3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.

Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.

Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).

Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC® Headache, sometimes severe, seems to be related to ZANTAC administration. Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain have been reported. There have been rare reports of malaise, dizziness, somnolence, insomnia, vertigo, tachycardia, bradycardia, premature ventricular beats, and arthralgias. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.

Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.

Although controlled studies have shown no antiandrogenic activity, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Incidents of rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia, have been reported, as well as rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.

OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.

DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)

Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.

HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
(NDC 0173-0362-38) 2-ml single-dose vials (Tray of 10)
(NDC 0173-0363-39) 10-ml multidose vials (Singles)
(NDC 0173-0362-01) 2-ml single-dose, prefilled, disposable cartridge-needle units (Tray of 10)
(NDC 0173-0362-00) 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

YOU CAN FIGHT CANCER BEFORE YOU GET IT.

OR AFTER YOU GET IT.

It's a lot easier to fight cancer before you get it.

Scientists estimate that up to 60% of all cancer could be prevented.

By simply making a few changes in your lifestyle.

By not getting too much sun. By not smoking cigarettes. By not overeating. And by following a diet high in fiber and low in fat.

By simply doing these few things, you could drastically reduce your risk of getting cancer.

Sure, you could still get cancer.

But why not give yourself the odds against it?

AMERICAN CANCER SOCIETY®
Help us keep winning.

THROMBOSTAT™ (THROMBIN, USP), a trusted hemostatic aid, is now available in a pump spray form—permitting flexible and easy application. With the new THROMBOSTAT pump, you can achieve hemostasis in seconds over large body surface areas. Each depression of the pump offers an even distribution

SPRAY ON HEMOSTASIS

of THROMBOSTAT solution—allowing uniform hemostasis of the total area. The THROMBOSTAT pump is available in a convenient sterile kit that features a 20,000-unit vial of THROMBOSTAT (a practical size for procedures involving capillary bleeding), an appropriate measure of diluent, and a pump sprayer cap. The kit offers sterile packaging—permitting the entire contents to be brought directly into the sterile field. With the new THROMBOSTAT kit, it has never been simpler to control capillary bleeding.

Please see next page for brief summary of prescribing information.

THROMBOSTAT™ (THROMBIN, USP) (Bovine Origin)

Before prescribing, please see full prescribing information. A Brief Summary follows:

Thrombostat must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE: Thrombostat (Thrombin, USP) is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery solutions of Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS: Thrombostat is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING: Because of its action in the clotting mechanism, Thrombostat must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Thrombostat is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS: General: Consult the absorbable gelatin sponge product labeling for complete information for use prior to utilizing the thrombin-saturated-sponge procedure.

Pregnancy—Teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical (Bovine). It is also not known whether Thrombin, Topical (Bovine) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical (Bovine) should be given to a pregnant woman only if clearly indicated.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: An allergic type reaction following the use of Thrombostat for treatment of epistaxis has been reported. Febrile reactions have also been observed following the use of Thrombostat in certain surgical procedures but no cause-effect relationship has been established.

DOSAGE AND ADMINISTRATION: General: Solutions of Thrombostat may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc, solutions containing approximately 100 units per ml are frequently used. For this, 10 ml of diluent added to the 1000 unit package is suitable. Where bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1000 to 2000 units per ml may be required. For this the 5000 unit vial dissolved in 5 ml or 2.5 ml respectively, of the diluent supplied in the package is convenient. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate volume of diluent. In many situations, it may be advantageous to use Thrombostat (Thrombin, USP) in dry form on oozing surfaces.

Caution: Solutions should be used the day they are prepared. The solution may be used for up to 6 hours when stored at room temperature; up to 24 hours when stored under refrigeration, and, if necessary, up to 48 hours when stored frozen.

The following techniques are suggested for the topical application of Thrombostat.

1. The recipient surface should be sponged (not wiped) free of blood before Thrombostat is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the Thrombostat mixes freely with the blood as soon as it reaches the surface.
3. In instances where Thrombostat in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried Thrombostat is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place.

Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP as follows:

1. Prepare Thrombostat solution of the desired strength.
2. Immerse sponge strips of the desired size in the Thrombostat solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

Thrombostat Kit: Thrombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. The Kit may be used as follows:

1. Remove the Tyvek blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared and the pump sprayer cap inserted and seated on the Thrombostat solution vial. Note: Several strokes of the pump sprayer will be required before the Thrombostat solution is expelled.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

Be prepared, Doctor. More patients will be asking about colorectal cancer. According to a survey* conducted by the American Cancer Society, many people would like to receive more information about colorectal cancer, and 83% said they would want to be checked for it. Further, they are learning that this cancer can be detected *before* symptoms appear. The present cure rate is 44%. The cure rate *could* be as high as 75%, with early detection and appropriate management.

For asymptomatic persons the Society recommends annual digital rectal examination at age 40 and over; at age 50 and over, an annual stool blood test, as well as sigmoidoscopy every three to five years, following two initial annual negative sigmoidoscopies.

We're here to help. You can reach us at your local American Cancer Society office or write to our Professional Education Department at National Headquarters, 90 Park Avenue, New York, N.Y. 10016. Ask about the Society's Colorectal Check program of professional and public education for the early detection of colorectal cancer.

Drug-induced Esophageal Strictures

LUIGI BONAVINA, M.D., TOM R. DEMEESTER, M.D., LAWRENCE MCCHESNEY, M.D., WERNER SCHWIZER, M.D., MARIO ALBERTUCCI, M.D., and ROBERT T. BAILEY, PHARM.D.

From the Department of Surgery, Creighton University School of Medicine, Omaha, Nebraska

A retrospective study of 55 patients with a benign esophageal stricture showed that in 11 patients (20%) the cause was a drug-induced lesion due to potassium chloride (3), tetracyclines (3), aspirin (2), vitamin C (1), phenytoin (1), and quinidine (1). Five of the 11 patients would have been diagnosed as having a reflux etiology of their stricture if 24-hour esophageal pH monitoring was not performed. Six patients responded to dilatation and five patients required resection or bypass. A prospective study of 18 asymptomatic volunteers showed a high incidence of esophageal lodgment of a radiolabeled medicinal capsule, with subsequent dissolution and release of the isotope. This occurred most frequently in elderly subjects and was reduced by increasing the volume of water chaser. The sites of lodgment correspond to the location of the observed strictures in the patient population. An *in vitro* study showed that, when the causative drugs were mixed with saliva, dissolution occurred within 60 minutes and was associated with significant changes in pH. These investigations show that drug-induced esophageal strictures are more common than previously appreciated, and can be confused with a reflux etiology. Diagnosis is suggested by a history of drug ingestion, location of the stricture, and a normal esophageal acid exposure on 24-hour pH monitoring. The severity of the esophageal injury is variable and requires dilatation to resection for therapy.

WITH THE INTRODUCTION of the 24-hour esophageal pH monitoring test into clinical practice it became evident that some patients, suspected to have a reflux stricture, did not show an increased esophageal acid exposure after dilation.[1] Because an understanding of pathogenesis is important for appropriate therapy, this finding stimulated the search for causes of stricture formation other than gastroesophageal reflux. In this search, two important observations were made from the literature. First, the number of reported esophageal injuries due to the ingestion of commercially available medications has steadily increased over the past 15 years.[2,3] Second, the ulcerogenic potential of several drugs on the esophageal mucosa has been demonstrated in animal models.[4,5] The purpose of this study was: (1) to establish the prevalence of drug-induced esophageal strictures in patients referred for surgical therapy, and (2) to investigate the pathophysiology of a drug-induced esophageal lesion.

Retrospective Clinical Study

Studied Population

From 1973 to 1986, 55 patients were referred to one of the authors (TRD) for treatment of a benign esophageal stricture. There were 30 men and 25 women, with a mean age of 57 years, ranging from 17 to 86 years. All patients complained of dysphagia and showed an esophageal stricture on roentgenographic barium study. Flexible esophagoscopy with multiple biopsies and brushing of the stricture was performed in all patients. When the stenosis appeared suspicious for malignancy and the initial biopsy showed a benign lesion, a more adequate biopsy specimen was obtained to exclude malignancy using the rigid esophagoscope. All biopsies showed esophagitis or fibrosis, and five patients had an associated Barrett's esophagus. Esophageal manometry and 24-hour pH monitoring were performed in patients whose strictures were successfully dilated up to a 60 French bougie.

Supported in part by a grant from the Health Future Foundation to the Creighton University Gastrointestinal Diagnostic and Research Center.

Submitted for publication: November 24, 1986.

Methods

Esophageal Manometry

Esophageal manometry was performed according to the technique described by Winans and Harris,[6] using a single-catheter assembly consisting of 3–5 fluid-filled polyethylene tubes bonded together with 3–5 lateral openings placed at 5.0-cm intervals from the distal end of the catheter and radially oriented 72–120 degrees apart. The diameter of the lateral openings was 2.0 mm in the three-lumen catheter and 0.8 mm in the five-lumen catheter. A constant infusion of distilled water was delivered initially by a Harvard infusion pump (Harvard Apparatus, South Natick, MA) through the three-lumen catheter, and subsequently, by an Arndorfer pneumohydraulic low compliance system (Arndorfer Medical Specialties, Inc., Greendale, WI) through the five-lumen catheter. The rate of infusion was 3.6 mL/min with the former and 0.6 mL/min with the latter. Studies obtained with the two infusion techniques were compared in a group of 14 subjects, and a correction factor was calculated to give uniformity of measurements between the two systems.

The catheter was passed into the stomach and withdrawn in 1.0-cm increments back into the esophagus, and from the esophagus into the pharynx. The overall length, the abdominal length, that is, the length below the respiratory inversion point, and the mean resting pressure of the distal esophageal sphincter were measured. Patients with a sphincter pressure of 6.0 mmHg or less, an overall sphincter length of 2.0 cm or less, and/or a length of sphincter exposed to intra-abdominal pressure of 1.0 cm or less were considered to have a mechanically defective cardia.[7] Distal esophageal sphincter relaxation was evaluated with five dry and five wet swallows, and was considered normal when the sphincter pressure dropped to the gastric baseline. The mean amplitude of the contractions, and the incidence of repetitive and simultaneous contractions in the distal esophageal body were noted during ten dry and ten wet swallows. Patients with a mean contraction amplitude of less than 20 mmHg and/or an incidence of repetitive or simultaneous waves greater than 30% were considered to have a nonspecific motility disorder of the esophageal body.[8] The length and mean resting pressure of the upper esophageal sphincter and the peak pharyngeal pressure were similarly measured.

Twenty-four hour Esophageal pH Monitoring

Twenty-four hour esophageal pH monitoring was performed according to a technique previously described,[1] with a pH electrode placed 5.0 cm above the upper border of the distal esophageal sphincter as measured by manometry. Acid reflux was defined whenever the pH in the esophagus dropped to 4 or less. Esophageal acid exposure was assessed by a composite mathematical score using EsopHogram software (Gastrosoft Inc., Milwaukee, WI) that incorporated six components of the 24-hour record: (1) percentage of time the esophageal pH was 4 or less for the total 24-hour period, (2) for the time in the upright position, (3) for the time in the supine position, (4) the total number of reflux episodes, (5) the number of episodes lasting 5 minutes or longer, and (6) the duration of the longest episode. Individuals whose cumulative score exceeded by more than two standard deviations the mean score of control subjects were considered to have an abnormal esophageal acid exposure.[9]

Investigation into the Cause of the Stricture

Based on the analysis of clinical history, endoscopic findings, and esophageal function studies, the patients were categorized as to the most valid cause for their stricture. Patients who had increased esophageal exposure to acid gastric juice on 24-hour pH monitoring were considered to have a reflux etiology. Patients who had a normal 24-hour pH study, or who were unable to have esophageal function studies performed, were intensely investigated for further clues regarding the cause of their stricture, including a complete history of drug consumption before the onset of the dysphagia.

Results

Twenty-four-hour esophageal pH monitoring showed an abnormal esophageal acid exposure in 41 (79%) of the 52 patients studied. These patients were considered to have a reflux etiology for their stricture.

Eleven patients had a normal 24-hour pH study and three patients could not be studied because of the inability to dilate the stricture in two patients and the presence of a Zenker's diverticulum in one patient. Table 1 shows the pertinent clinical information obtained from these 14 patients by focused questioning, endoscopy, and, when possible, esophageal manometry. The evidence suggested that the cause of the stricture was drug injury in 11 patients, alkaline reflux after gastrectomy in two patients, and gastroesophageal reflux in one patient. Thus, 11 of the initial 55 patients had strong evidence for a drug-induced stricture. This represents a prevalence of 20% in the overall referred population.

Seven of the 11 patients with a drug injury had underlying esophageal pathologic conditions. Four patients had an esophageal motility disorder, three patients had a greater than 30% incidence of repetitive and simultaneous contraction on swallowing, and one patient showed aperistalsis of the esophageal body with incomplete distal esophageal sphincter relaxation. Three other

11	Quinidine	4 mos	Dilatation (N = 1)	Good (3 mos)

patients had roentgenographic esophageal abnormalities that could potentially interfere with transit of a drug through the esophagus: these were two patients with a Schatzki's ring and one patient with a hiatal hernia and gastroesophageal reflux.

Table 2 summarizes the drug history and therapy of the 11 patients considered to have a drug etiology of their stricture. All of the patients were initially treated with dilatation. This was successful in six patients, with the number of dilatations ranging from 1–45. Dilatation was of temporary benefit in three patients and unsuccessful in two. In one of these five patients the dilatation resulted in a perforation and required resection of the esophagus and colon interposition. In another patient esophageal resection and colon interposition was required to establish oral alimentation (Fig. 1). In the third patient, because of operative risk factors, a substernal colon bypass of the strictured esophagus was performed (Fig. 2). In the fourth patient, because of the localized disease, a sleeve resection of the esophagus was performed (Fig. 3). The fifth patient had excision of a fibrous ring and an esophageal myotomy, but required a substernal colon bypass to the pharynx when the stricture reoccurred. (Fig. 4). The specimen in the two patients who had esophagectomy showed mucosal ulceration and panmural fibrosis at the stricture site (Fig. 5). Results of surgery were satisfactory in all patients except for the patient who had the sleeve resection. In this patient, the procedure resulted in pulling the esophagus up into the thorax causing a reduction of distal esophageal sphincter pressure, a decrease of abdominal sphincter length, and the induction of gastroesophageal reflux confirmed by 24-hour pH monitoring (Table 3).

Prospective Clinical Study

Studied Population

Eighteen individuals volunteered for a prospective study designed to evaluate the probability for a medicinal capsule to lodge in the esophagus. The volunteers were free of clinical disease as judged by history and physical examination. There were 11 men and seven women. The population was divided into two age groups. Nine volunteers were under 70 years of age (mean age: 32 years, range: 21–49 years), and nine were over 70 years (mean age: 76-years, range: 71–81 years). The reason for dividing the population at this age was the decline in the amplitude of esophageal contractions observed in individuals over the age of 70.[10] In each volunteer, the esophageal transit time of a gelatin capsule containing radioactive material was measured when ingested with a small- and large-volume water bolus. Twelve of the 18 volunteers consented to esophageal manometry.

Normal values for esophageal motility were obtained from a group of 20 control subjects, 10 men and 10 women, with a mean age of 38 years, ranging from 20–71 years. All control subjects were free of esophageal disease as assessed by history, barium roentgenographic study, and 24-hour esophageal pH monitoring.

Methods

Esophageal Transit Scintigraphy

A radionuclide marker was placed over the cricothyroid notch of each volunteer or control subject to denote the position of the cricopharyngeus, *i.e.*, the esophageal inlet. A 25-mL bolus of water labeled with a 250-μCi dose of Tc-99M sulfur colloid solution was administered orally to define the esophageal anatomy.[11] Images were obtained every 0.3 second for 60 seconds with the subject initiating dry swallows at 15-second intervals. Computerized composite imaging was used to develop an anatomic picture of the esophagus, esophagogastric junction, and stomach. This allowed for accurate placement of computer-generated regions of interest.

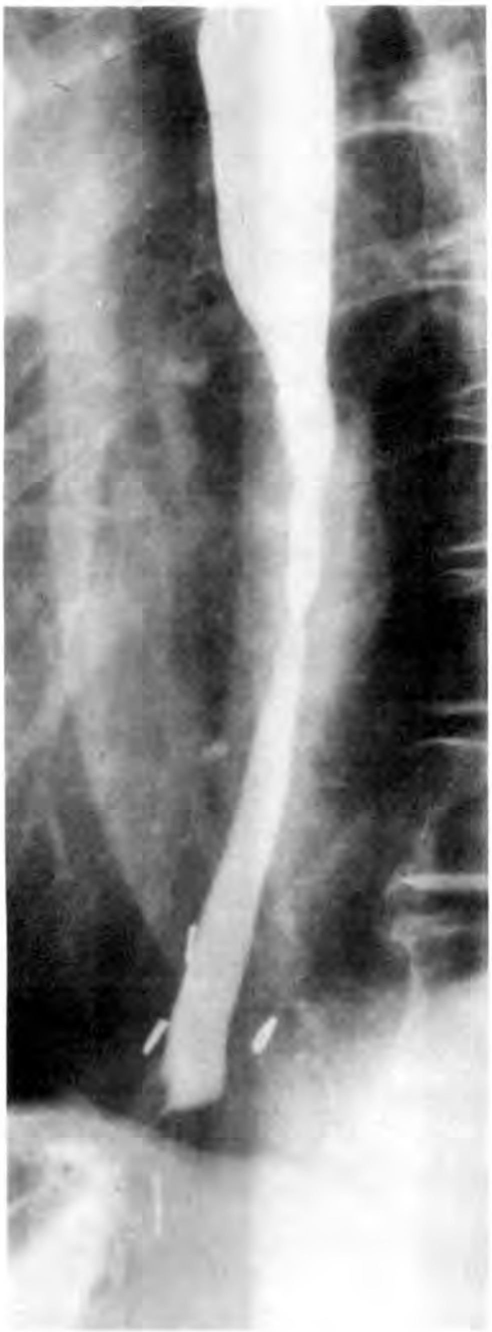

FIG. 1. Barium esophagogram in patient 1 with achalasia showing midesophageal stricture secondary to ingestion of potassium chloride. The degree of tissue injury is reflected by the thickness of the companion shadow. The hemostatic clips are from a previous Heller myotomy. The stricture was unable to be dilated and an esophageal resection with colon interposition was performed. Histologic examination of the surgical specimen showed squamous epithelium above and below the strictured segment.

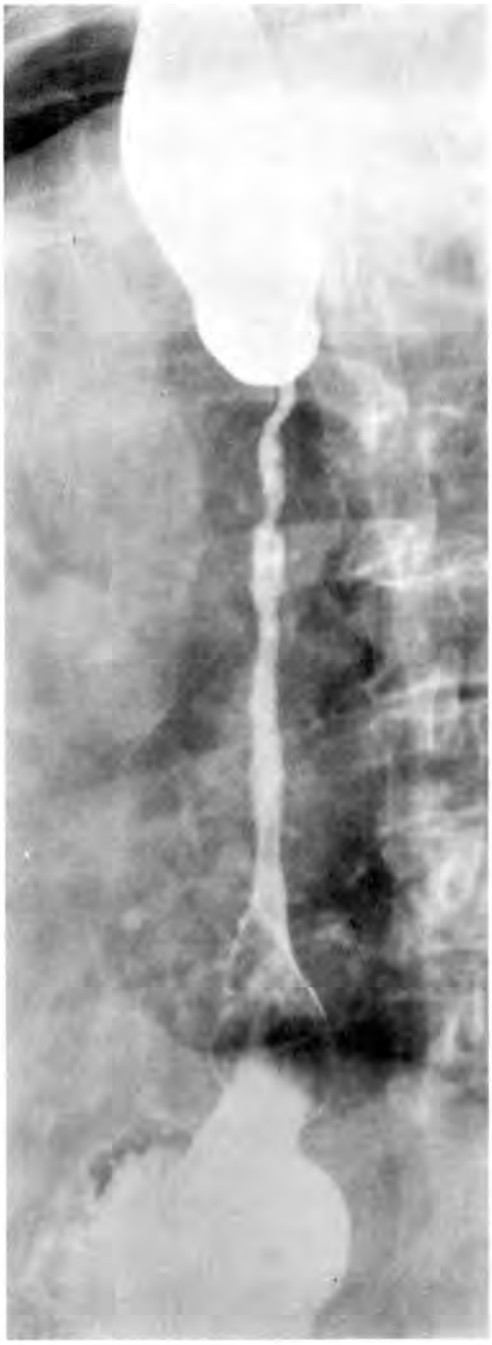

FIG. 2. Barium esophagogram in patient 6, showing a long esophageal stricture secondary to gastroesophageal reflux and the ingestion of potassium chloride. Note the presence of a hiatal hernia. The stricture was unable to be dilated, and because of the patient's age and physiologic status, a substernal colon bypass was performed.

A radiolabeled gelatin capsule was prepared by adding

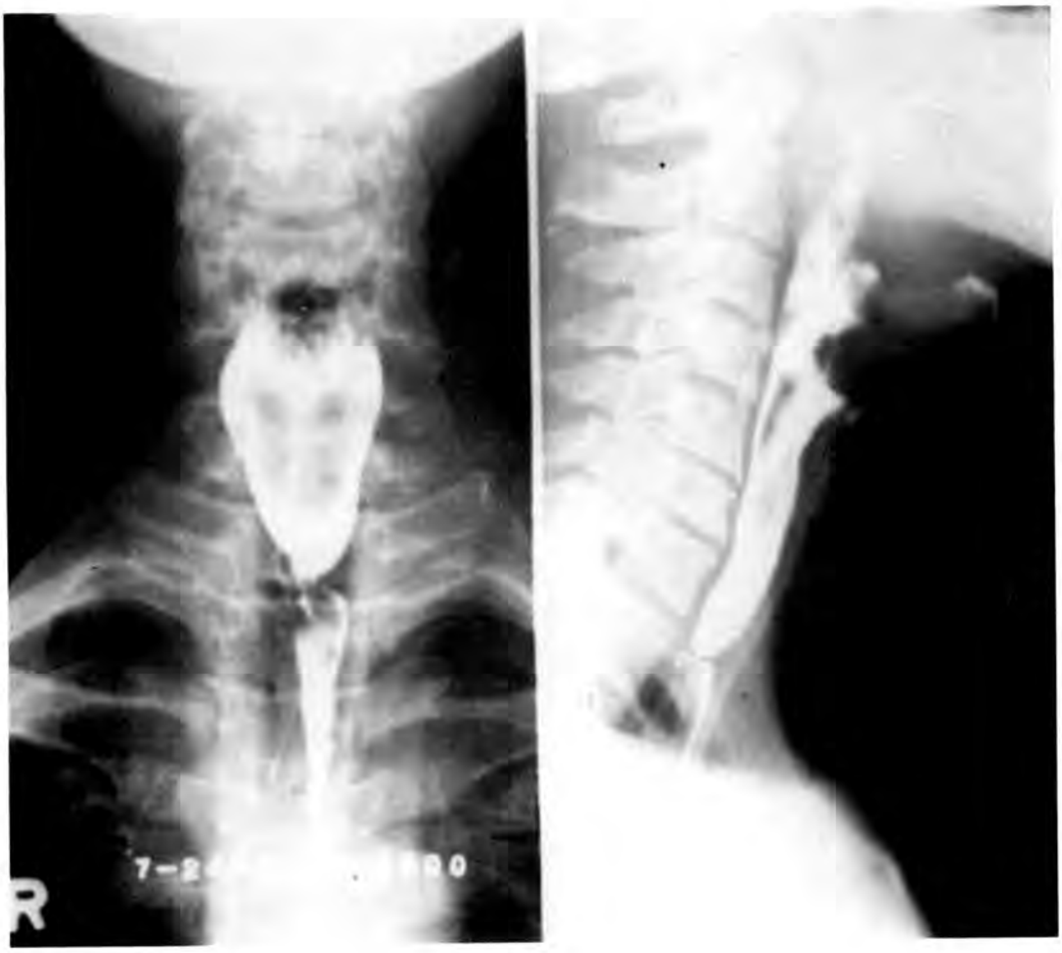

FIG. 3. Barium esophagogram in patient 8, showing a short esophageal stricture in the upper esophagus secondary to ingestion of phenytoin. Dilatation did not relieve dysphagia and the stricture was excised by a sleeve resection of the esophagus. This resulted in gastroesophageal reflux.

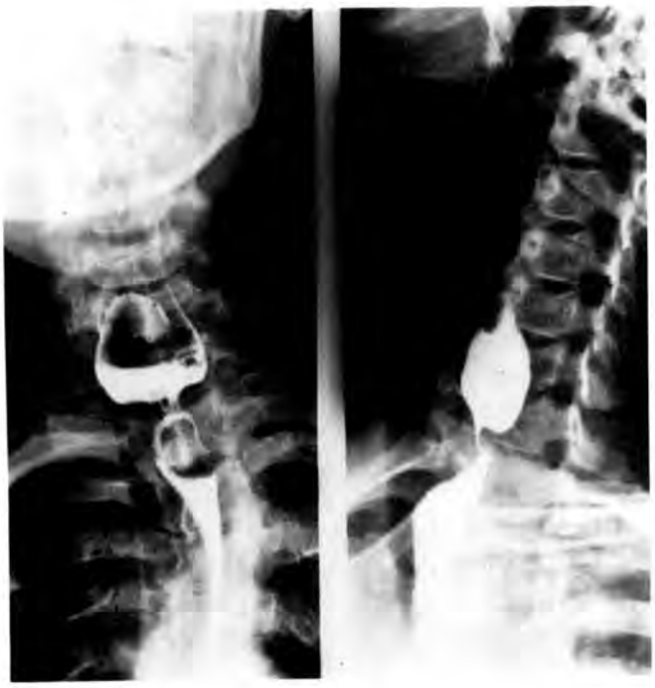

FIG. 4. Barium esophagogram in patient 9, showing a high esophageal stricture secondary to ingestion of doxycycline. Excision of a fibrous ring and an esophageal myotomy were initially performed. Dysphagia recurred in 4 years, requiring a substernal colon bypass to the pharynx.

a 250-μCi dose of Tc-99M sulfur colloid solution to the inside lumen of an empty soft #2 gelatin capsule. This capsule was then progressively nested inside a #1, #0, and #00 empty soft gelatin capsule. The final product was a #00 radiolabeled gelatin capsule weighing 1.06 g with a barrier of four layers of gelatin between the internal liquid contents and the outer capsule environment. This technique was used to prolong capsule dissolution and subsequent release of the radiolabeled internal liquid contents for up to 10 minutes. It also provided additional weight to the capsule to simulate more closely the density of most commercially available medicinal capsules.

The volunteers were instructed to swallow the radiolabeled gelatin capsule with a 120-mL water bolus while in the upright position. Images were obtained every 0.3

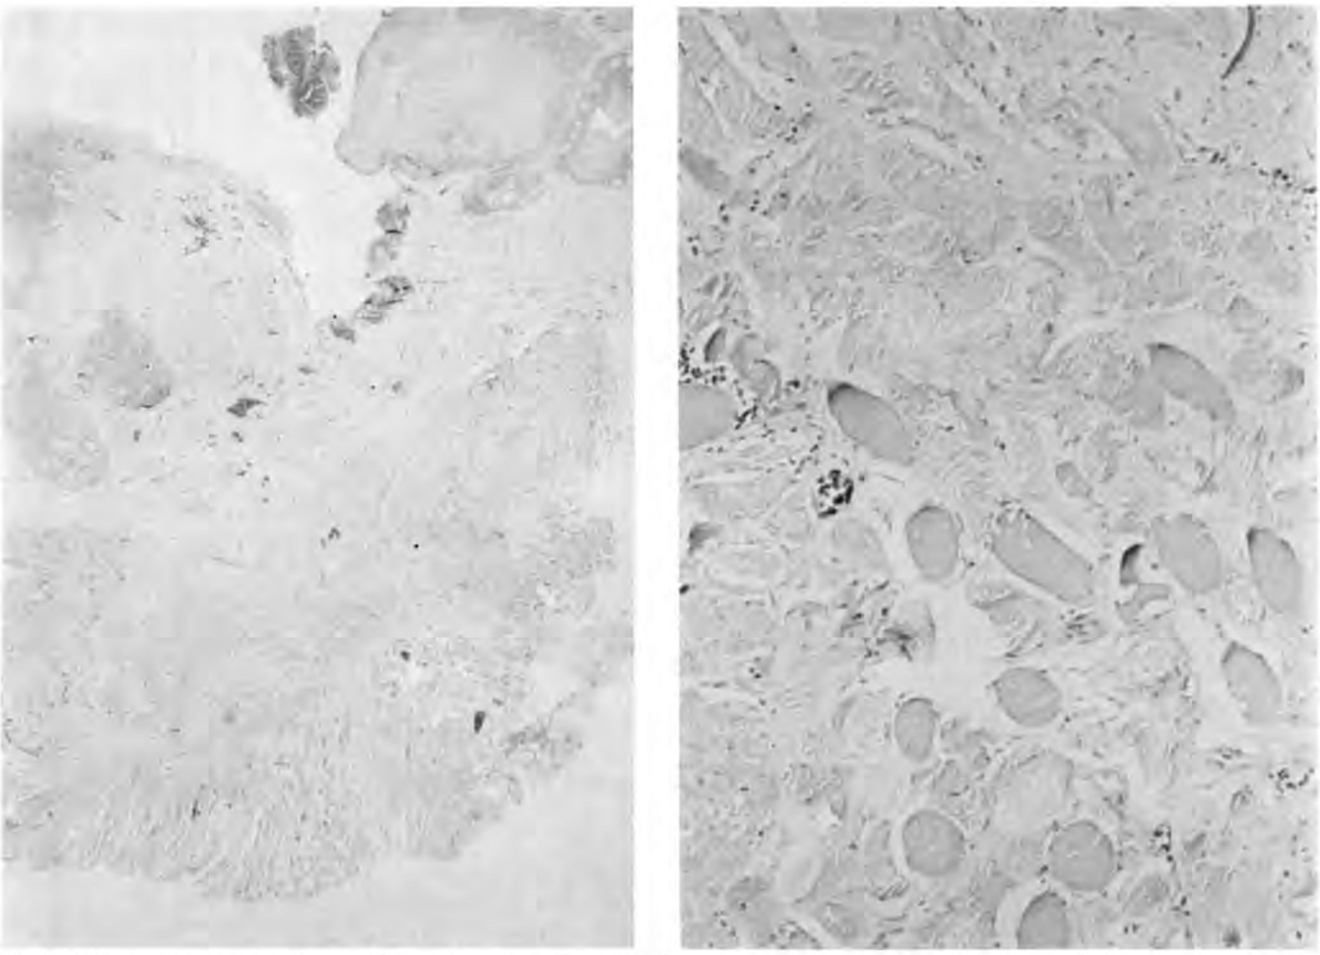

FIG. 5. *Left.* microphotograph of the surgical specimen of patient 8, showing an esophageal ulcer with transmural fibrosis (hematoxylin and eosin, original magnification ×10). *Right.* higher magnification (original magnification ×250) of esophageal muscle fibers with intramural fibrosis. The degree of tissue damage explains the failure of dilatation to relieve dysphagia.

second for 60 seconds with the individuals swallowing at a 15-second interval. Additional images were obtained at 2-minute intervals for up to 10 minutes when the capsule lodged in the esophagus to document the eventual passage of the capsule or its dissolution with the release of the radionuclide solution into the esophagus. The same procedure was then repeated in all volunteers using an identically prepared radiolabeled gelatin capsule administered with only a 15-mL water bolus.

Esophageal Manometry

The methods are the same as described for the retrospective clinical study.

FIG. 6. Lodgment of the gelatin capsule in the esophagus with dissolution of the gelatin and release of the radionuclide into the esophageal lumen. Capsule was ingested with a 15-mL bolus of water.

Results

Esophageal Transit Scintigraphy

The capsule given with the 15-mL water bolus lodged in 11 of the 18 volunteers (61%), at the level of the aortic arch in seven (Fig. 6) and at the gastroesophageal junction in four. Figure 7 shows that the capsule lodgment occurred at sites similar to the location of the drug-induced esophageal strictures in the 11 patients reported in Table 2. The capsule lodged in five of the nine volunteers under the age of 70, and in six of the nine volunteers age 70 or greater.

When the 120-mL water chaser was used, lodgment occurred in three (17%) of the 18 volunteers, at the level of the aortic arch in one and at the gastroesophageal junction in two. All three of these volunteers were over 70 years of age. The capsule did not lodge in any of the volunteers under the age of 70 when taken with 120 mL of water.

Overall, the capsule lodged in 11 of 18 volunteers. In three of the 11, lodgment occurred even when the volume of water chaser was increased to 120 mL. The incidence of capsule lodgment with the 15-mL bolus statistically differed from the incidence of capsule lodgment with the 120-mL bolus (61% *vs.* 17%, $p < 0.005$). Thus, increasing the volume of water chaser caused a decrease in the incidence of capsule lodgment by 44%.

Esophageal Manometry

In the 12 volunteers examined, the mean distal esophageal sphincter pressure, the degree of sphincter relaxation, and the mean amplitude of esophageal contractions on dry and wet swallows did not statistically differ from the reference values obtained from the control subjects. Three of the 12 volunteers had a nonspecific esophageal motility disorder, *i.e.,* a greater than 30% incidence of repetitive or simultaneous contractions. All three were over 70 years of age. In one of the three, the capsule lodged with the 120-mL water chaser. Volunteers in whom the capsule lodged with the 120-mL bolus showed a lower mean amplitude of esophageal contractions with wet swallows, compared with those in whom the capsule lodged with only the 15-mL bolus ($p = 0.05$), suggesting they had less propulsive force in the body of their esophagus.

In Vitro Experimental Study

Methods

An *in vitro* evaluation of dissolution time was performed on the drugs responsible for the esophageal le-

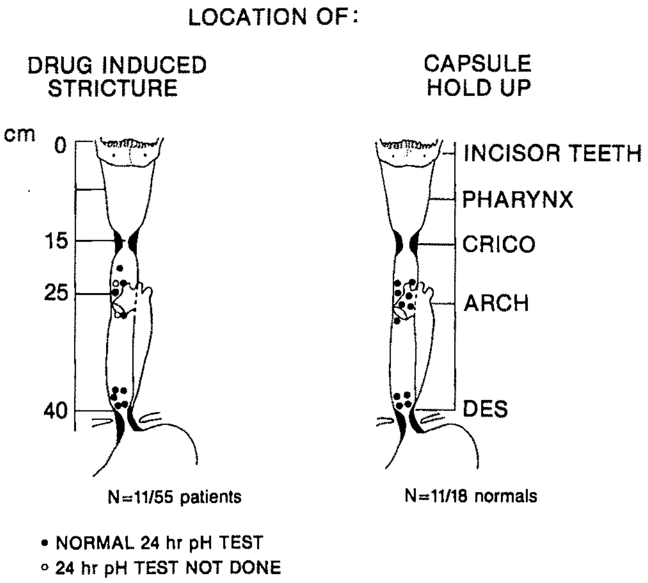

FIG. 7. Schematic drawing of the esophagus showing that the site of capsule lodgment in 11 volunteers after a 15-mL water chaser was similar to the location of drug-induced stricture in the 11 patients reported in Table 2.

TABLE 4. *Dissolution Time and pH of Drugs Observed to Cause Esophageal Injury*

	pH Saliva	Start Dissolution Time (Min)	Complete Dissolution Time (Min)	pH at Complete Dissolution
Potassium chloride, 750 mg (slow-release tablet)	6.3	—	>720	6.5
Potassium chloride, 750 mg (elixir)	6.4	—	—	6.6
Doxycycline hyclate, 100 mg (capsule)	6.1	7.0	37	3.2
Tetracycline hydrochloride, 250 mg (capsule)	6.2	10.0	42	1.6
Acetylsalicylic acid, 325 mg (tablet)	6.3	1.5	5	3.4
Ascorbic acid, 500 mg (tablet)	6.2	1.0	58	2.8
Phenytoin sodium, 100 mg (capsule)	6.1	8.0	15	10.4
Quinidine gluconate, 324 mg (sustained-release tablet)	6.4	—	>720	6.9

sion in the 11 patients. A standard dose of medication was placed in a test tube containing 10 mL of saliva. The time was noted when dissolution of the capsules or tablets started and when completed. The pH of the saliva was recorded throughout the course of the experiment using a Beckman pH electrode (Beckman Instruments, Inc., St. Louis, MO) connected *via* a pH meter to a strip chart recorder running at a speed of 2.5 cm/min.

Results

Table 4 shows that, with the exception of potassium chloride and quinidine, the slow-release tablets, dissolution of all preparation started within 10 minutes, was completed by 60 minutes, and was associated with a marked shift in pH. No pH change was observed with potassium chloride and quinidine, suggesting that local concentration of a drug is the important factor in producing mucosal damage.

Discussion

We were surprised that 11 (20%) of the 55 patients referred for therapy of a benign esophageal stricture had a drug-induced etiology. In six of the 11 patients, this was suggested by the location of the stricture and/or a normal 24-hour pH test. In five patients, the drug-induced stricture was located in the distal esophagus and would have been assumed to be due to gastroesophageal reflux if the 24-hour pH study had not been normal. This suggests that the true incidence of drug-induced esophageal strictures in patients referred for surgery is probably underestimated, since it is common practice to assume gastroesophageal reflux as the cause when the stricture is located in the distal esophagus.[12]

A drug etiology for an esophageal stricture should be considered when, after dilatation, the patient has a normal esophageal acid exposure on 24-hour pH monitoring and a history of drug ingestion. When there is no history of drug ingestion, other causes for the stricture must be investigated. The most common is alkaline gastroesophageal reflux in a patient with achlorhydria[13] or previous gastric surgery.[14]

Over the past 15 years, clinical and experimental reports have shown that lodgment of ingested pills in the esophagus can occur,[15,16] and that a variety of medications can produce esophageal injury[3,4] (Table 5). Initially, a drug-induced esophageal injury was believed to be limited to subjects with underlying esophageal pathologic conditions. Subsequently, it became evident that most patients with the problem were apparently free of esophageal abnormalities.[3] This focused investigation on factors that influenced the transit of tablets or capsules through the esophagus, such as the position of the body on swallowing, the density, size, and shape of the capsules or tablets, and the volume of the fluid chaser.[16] Medications known to be corrosive, such as potassium chloride, have been prepared in a powder form or slow-release tablets to avoid a high localized concentration. Despite these efforts, drug-induced esophageal injury still remains a complication of medicinal therapy. The *in vitro* study reported showed that most medications with a potential for causing esophageal injury, when mixed with saliva, have a dissolution time within 60 minutes. This property, plus the holdup of tablets or capsules in the esophagus, can result in tissue injury

from a high localized drug concentration at an excessive pH. Prevention will require the design of a capsule or tablet to reduce their tendency to lodge in the esophagus, and better chemical formulation of the medication to prevent high local concentrations. This may be achieved by the development of large chewable pills with less drug concentration and a more neutral pH.

In our prospective study the main predisposing factors for lodgment of a capsule in the esophagus were the volume of the water chaser and the age of the subject. Individuals over 70 years of age had a decrease in the amplitude of esophageal contractions. Even when a full glass of water was given with the medication, one third of these individuals had the capsule lodge in the esophagus. Consequently, educating patients to take medications with a full glass of water will reduce the incidence of lodgment but is unlikely to eliminate the problem.

As one would expect, patients with underlying esophageal abnormalities are prime candidates for a drug-induced esophageal injury, and a special effort in preventive education should be extended to them. The presence of an esophageal abnormality, such as a motility disorder, hiatal hernia, Schatzki's ring, or reflux-induced esophagitis and stricture, can increase the probability of capsule or tablet lodgment. The former two are associated with an increased transit time[17,18] and the latter two are known causes for holdup of solids in the distal esophagus.[19,20] We suspected in one of our patients that the combination of reflux esophagitis and entrapment of a medicinal tablet contributed to the development of a severe stricture that could not be forcibly dilated. Most reflux-induced strictures can be dilated since the fibrosis is limited to the submucosa. When there is transmural fibrosis, as in lye strictures, dilatation often cannot be accomplished, or if so, is often ineffective in relieving the symptoms of dysphagia. When a stricture that appears to be due to reflux cannot be dilated or the results of dilatation are unsatisfactory, the possibility of a superimposed drug injury should be investigated.

Open heart surgery may also predispose to drug-induced esophageal injury.[2] We believe that esophageal clearance was adversely affected in one of our patients by hypothermia of the esophageal muscle during coronary artery bypass, and compression of the distal esophagus by the heart after its pericardial support has been lost by the pericardiotomy. In this situation, potassium chloride, even in the liquid form, may not be cleared from the esophagus especially in the supine position.

Patients with a drug-induced esophageal stricture do not require an antireflux repair. In most situations, dilatation of the stricture is sufficient to relieve dysphagia. In a review of drug-induced esophageal injury, Oakes and Sherck reported 17 strictures, all of which responded to dilatation.[21] This therapy was successful in six of our 11 patients, even though one patient required 45 dilatations over a 2-year period. In the other five patients, an attempt to dilate the stricture was unsuccessful and in one patient resulted in perforation of the esophagus. The inability to dilate the stricture is an indication for esophageal resection with colon interposition. The resected surgical specimens from these patients showed dense full-thickness fibrosis, and reflect the severity of the esophageal injury that can be caused by drugs. In older patients with high surgical risk, or in patients with extensive fibrosis at the stricture site, a substernal colon bypass can be performed. A limited esophageal sleeve resection may represent a tempting solution for localized short strictures, but the potential for causing gastroesophageal reflux, secondary to increased longitudinal tension and loss of intra-abdominal esophagus, should discourage its use. This was well documented in one of our patients and has convinced us of the inadvisability of this approach.

During the course of this study, it has occurred to the authors that the well-known but poorly understood esophageal web of the Plummer–Vinson syndrome may actually be a drug-induced lesion. Since these patients have an iron deficient anemia, it would be logical for physicians to prescribe ferrous sulfate, a drug known to cause esophageal injury (Table 5). It is reasonable to suspect that a number of such patients may have had a drug-induced esophageal injury develop at the site where the web is commonly observed. Not knowing the cause of the esophageal abnormality, the early observers reported the web as part of the syndrome.[22]

Esophagectomy Without Thoracotomy: Is There a Risk of Intramediastinal Bleeding?

A Study on Blood Supply of the Esophagus

DOROTHEA M. I. LIEBERMANN-MEFFERT, M.D., URS LUESCHER, M.D., URS NEFF, M.D.,
THOMAS P. RÜEDI, M.D., F.A.C.S., and MARTIN ALLGÖWER, M.D., F.R.C.S.(HON), F.A.C.S.(HON)

From the University Hospital Basel, Kantonsspital Basel, and Kantonsspital Chur, Switzerland

In transhiatal blunt esophagectomy there is surprisingly little bleeding if no adjacent great vessels are torn. This prompted an investigation by new injection techniques and corrosion on the human esophageal vasculature three-dimensionally. The three main arterial sources were confirmed: the superior thyroid artery, bronchial arteries at the level of the carina, and the left gastric and splenic artery. Two facts became obvious that were not appreciated hitherto. All major vascular trees divide into minute branches at some distance from the esophagus. Those branches go on to form a dense submucosal interconnected network. It appears that such small extraesophageal branches, when torn, will have the benefit of contractile hemostasis. Previous claims made that essential nutritional vessels arise from intercostal phrenic arteries or the aorta directly could not be confirmed. These findings would confirm blunt esophagectomy for tumors within the wall of the organ as a relatively safe procedure in terms of bleeding hazards.

THE BLUNT PULL through esophagectomy without thoracotomy for esophageal lesions with cervical esophagogastric anastomosis initially proposed by Denk[1] and successfully done in humans by Grey-Turner[2] has fallen in almost complete oblivion but recently found an increasing number of advocates.[3–7] It is described as a relatively safe approach with moderate blood loss[8–15] (see also Table 1). It appears to greatly reduce the danger of septic mediastinitis caused by anastomotic leakage. The three decades of oblivion have most likely been caused by two facts: the advent of safe thoracotomies has placed emphasis on direct approach to the organ with intrathoracic esophagogastro or esophagojejuno anastomoses. Although this currently appears to be a procedure with acceptable mortality rates, it remains that any anastomotic leakage in the thorax is a life-threatening complication.[8,16–18] The second reason for discontinuing the use of blunt esophageal dissection were schemes of vascular supply of the esophagus in textbooks of anatomy and surgery that suggested major arteries supplying the esophagus from the intercostal vessels and directly from the aorta. In view of those schemes it seemed extremely hazardous to engage in any blunt dissection of such a well-vascularized organ.

The relatively few investigators of human esophageal vascularization referred to classical macroscopic assessment at autopsy and therefore only reported on the larger stem vessels.[19–21] Intramural anastomoses shown by fluoroscopy after *in situ* barium injection[19,22] did not outline well the arterial pattern because of the overlying arteries of adjacent structures.[23] This also holds true for angiography *in vivo*.[24] The technique of corrosion casts,[25] which produces realistic, three-dimensional replicas of the vascular system of small solid organs, was not used for large hollow organs such as the esophagus and stomach. This technique, when properly modified, was hoped to clearly display both the large extraparietal arterial sources as well as the details of the microvascular connections and provide the answer to the following three questions: (1) Can the classical vascular sources of arterial blood supply to the esophagus: cervical, thoracic and abdominal, be confirmed? (2) What is the microvascular pattern of arterial blood supply to the esophagus and how much interconnection exists between the arterial territories of the esophagus? (3) How is it that in the face of a fairly large size of mediastinal arterial source (the bronchial artery) blunt dissection can be done without deleterious hemorrhage?

* Insignificant mediastinal hemorrhage was reported in three cases and hemothorax in 10 cases.

† Fatal bleeding from the azygos vein (AV) was a fatal complication and led to 0.7% intraoperative mortality rate.

‡ Problems concerning the recurrent laryngeal nerve were reported as being transient and only three times (−3) required reoperation.

§ Most anastomotic leaks closed spontaneously.

‖ Orringer's report of 1983 contains the patients of his report of 1978.

Materials and Methods

Eighteen human specimens were subjects of this study; 11 were male and seven were female, aged 36–80 years. All subjects with a previous abdominal history, vascular disease, or diabetes were excluded. Sixteen of the specimens were injected with the resin Beracryl (Acryl-Industrie-Kunststoff, Troller AG, CH 4854 Fulenbach, Switzerland) and two specimens were injected with Mercox-(Vilene Co., Ltd., Tokyo, Japan).

Preparation

At autopsy, 9–24 hours postmortem, a large specimen containing the upper intestinal and chest organs, the tongue, a 15-cm cuff of diaphragmatic muscle, and the entire aorta was removed *en bloc.* We took great care not to avulse the intercostal arteries from the aortic origin, preserving stumps of at least 2–4 cm in length. The heart was dissected close to the aortic valve; lungs, liver, spleen and kidneys were removed at the organ hilum. We secured a Foley catheter (Rüsch® 22-26 Charriere, Switzerland) in the caudal aorta (Fig. 1) and irrigated the vessels with deaerated water to which Heparin (Liquemine®) was added to remove clots. Torn or divided collaterals from adjacent organs were detected by leakage of fluid and ligated. Ligature of the cranial aorta established a closed circuit.

To stabilize the intestinal cavities and to avoid collapse of the esophagus and stomach during the subsequent procedures, we placed an intestinal tube into the esophagus and a balloon (condom) into the stomach. This balloon was filled with water.

Injection

We used two resins of different viscosity: (1) For the macroscopic display of the arteries, the synthetic cold-

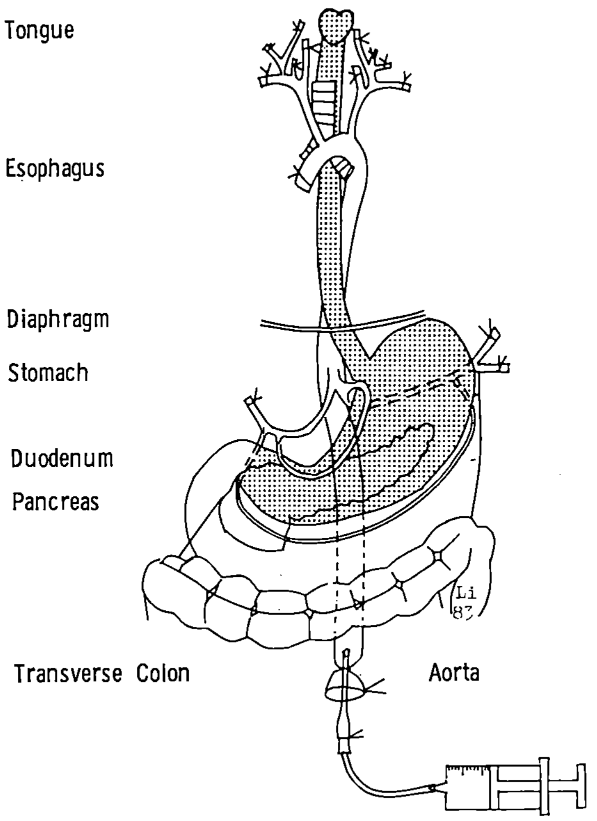

FIG. 1. *En bloc* specimen ready for Beracryl injection with Foley catheter in the aorta. All arteries supplying organs other than shown were ligated.

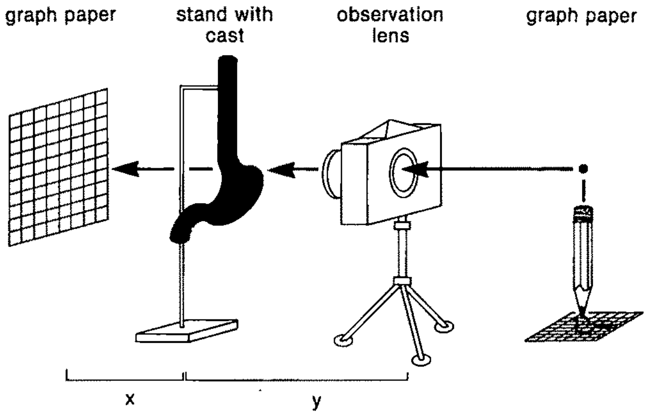

FIG. 2. Method of reproduction of the arterial tree. The cast was placed in front of the graph paper and its dimensions transferred on a second graph paper as viewed through a lens. The distances between cast and graph paper (x) and lens (y) were constant in all the reproductions.

setting Beracryl was used. This fluid polymer/solid monomer catalyst had powder particles of 160 μm, thus allowing flow into arteries of 0.2–0.1 mm internal diameter. Through the Foley catheter we injected by hand 400–500 mL of the liquid until a clear resistance occurring after 5 minutes indicated the completeness of the injection. (2) For the display of the microcirculation, the synthetic cold-setting Mercox was used. This product had a viscosity that allowed flow through the arteries and through the capillaries into the veins. However, its use is limited to specimens of small size.[26] Therefore, the left gastric artery was injected; 150 mL of the resin were needed.

Care was taken not to stir air into the resins while mixing the components; we did not use machines for injection[25,27] because this caused burst of vessels in our previous studies.[23,28,29]

During the injection and the subsequent procedures, the specimens were submerged in a large container (55 × 40 × 25 cm), filled with 10–15 L of lukewarm water; any change in position was avoided. After 20 minutes we added formaldehyde to make a 5% solution, in which the casts remained until they were fully hardened 12–20 hours later. Shrinkage of the entire specimen was 1–3%.

Corrosion

We changed the formaldehyde solution for 30% caustic soda and placed the container in a water tank (Mazerationsanlage, Fa. Handschin, CH 4000 Basel, Switzerland). Being at a constant fluid temperature between 50 and 60 C, the organic tissues of the specimens were macerated after 15–30 hours. The vascular cast was rinsed in water, carefully cleaned, and mounted on a stand to air dry. To ensure that the casts had not been damaged, we routinely filtered the content of the containers for residuals.

Documentation

The casts on their stand were photographed and sketches were also made. To this effect, they were placed at a distance of 30 cm in front of a large sheet of graph paper and carefully recorded as illustrated in Figure 2.

The various diameters of the vessels were measured using a binocular magnifier. These were compared with gastric, pancreatic, and middle colic vessels. The values obtained from the casts refer to the internal diameter of an artery and, therefore, the arteries seem to be of smaller size than those observed during surgery.

The clean Mercox casts were cut in suitable small blocks and mounted on stubs with glue. The blocks then were gold sputtered and inspected in a stereoscan. SEM photographs were taken of the various aspects (Dr. Düggelin, REM Labor, Universität Basel, Switzerland).

Results

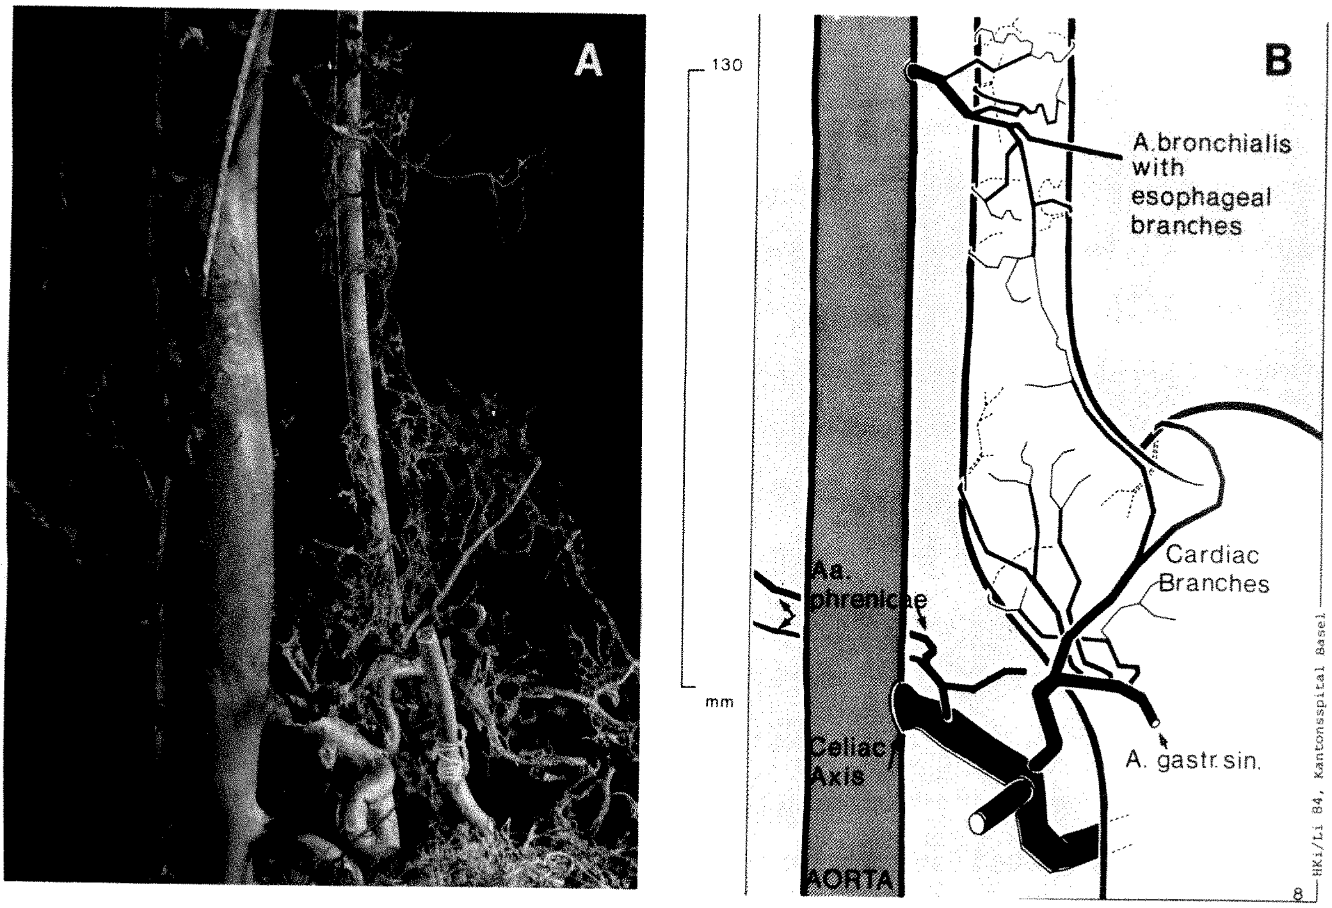
The esophagus ranged from 24 to 34 cm in length (cricoid to cardia) with an average of 27.6 cm. The mean distance between the celiac axis and the aortic arch was 23 cm in the postmortem specimen and this did not differ from the corrosion cast.

Corrosion Cast

The casts contained the complete arterial tree of the tongue, esophagus, stomach, greater omentum, and pancreas. The esophagus was easy to discern by virtue of the intraluminal tube placed at autopsy and by the tubular arrangement of its small vessels. These formed arterial anastomoses (Figs. 3 and 4) but often was incomplete in Beracryl casts because these casts did not display the fine arteriolae retae. The microvasculature was shown with the Mercox cast and found to be a dense network of minute arterioles located in the tela submucosa and tunica mucosa without any interruption throughout the esophagus (Fig. 5).

Cervical Esophagus

The blood supply of the upper esophagus was provided by branches from both the right and left superior and the inferior thyroid arteries (Fig. 6). Compared with the esophageal vessels, the superior thyroid arteries were rather larger caliber vessels, the right being 2.0 mm, the left 1.5 mm internal diameter at their origin. The esophageal branches were 2–3 cm in length before dividing in small branches. These branches ran to the lateral aspect of the esophagus and anastomosed anteriorly and posteriorly. In one of the 16 specimens there was one singular esophageal branch from the subclavian artery.



FIGS. 3A and B. Arterial tree of the middle and lower esophagus. Beracryl specimen. *A*. Corrosion cast, right lateral aspect with intraesophageal catheter (c). In this example, three stem vessels supplied the intrathoracic esophagus: the bronchial artery, the left gastric artery, and the splenic artery. All these gave rise to several small esophageal branches (<1 mm diameter). The inferior phrenic artery (fat arrows) arose from the celiac axis and supplied exclusively the diaphragm. Stumps of the intercostal arteries are seen alongside the aorta (small arrows) with no branches to the esophagus. *B*. The diagram simplifies the arterial distribution. The vessels supplying the posterior wall of the esophagus are shown as dotted lines.

Intrathoracic Esophagus

The caudal aspect of the aortic arch had up to four vessels of 1–2.5 mm diameter (Figs. 7 and 8). These mainly supplied the trachea, but gave off up to six small branches to the esophagus. Just below the arch, one unpaired artery of 1–3 mm caliber regularly arose from the anterior aspect of the aorta. This divided into one tracheobronchial and one or two small esophageal arteries 0.3–0.5 mm in diameter (Fig. 3). Additional unpaired small arteries arose at variable locations from the anterior wall of the aorta: seven casts had one, three casts had two such arteries, and six casts had none at all. The aortic arteries ran to the posterior aspect of the esophagus and were 1.5–6 cm apart. Although their caliber

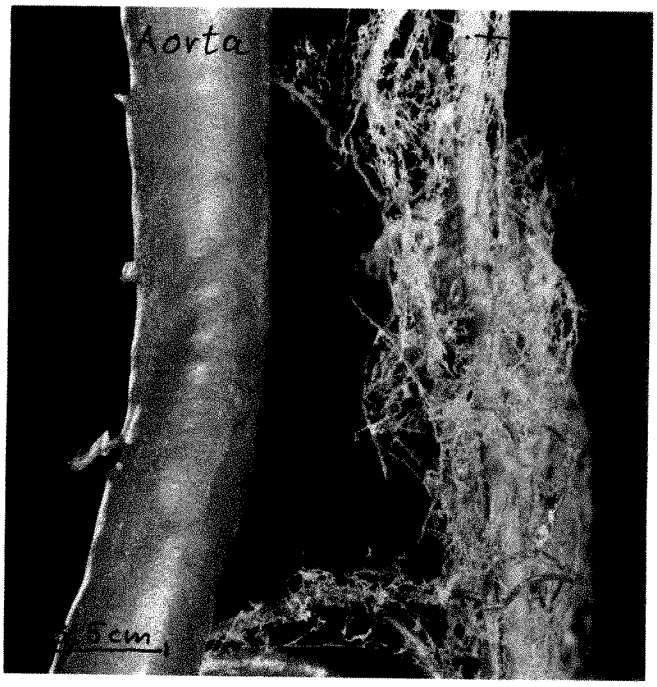

FIG. 4. Arterial vascularization of the middle and lower esophagus. Beracryl specimen, dorsolateral aspect with left gastric and splenic artery below and aortic vessel above. A catheter is still in place in the esophageal lumen. Note the small diameter of the esophageal vessels that divide into the microvascular submucosal network.

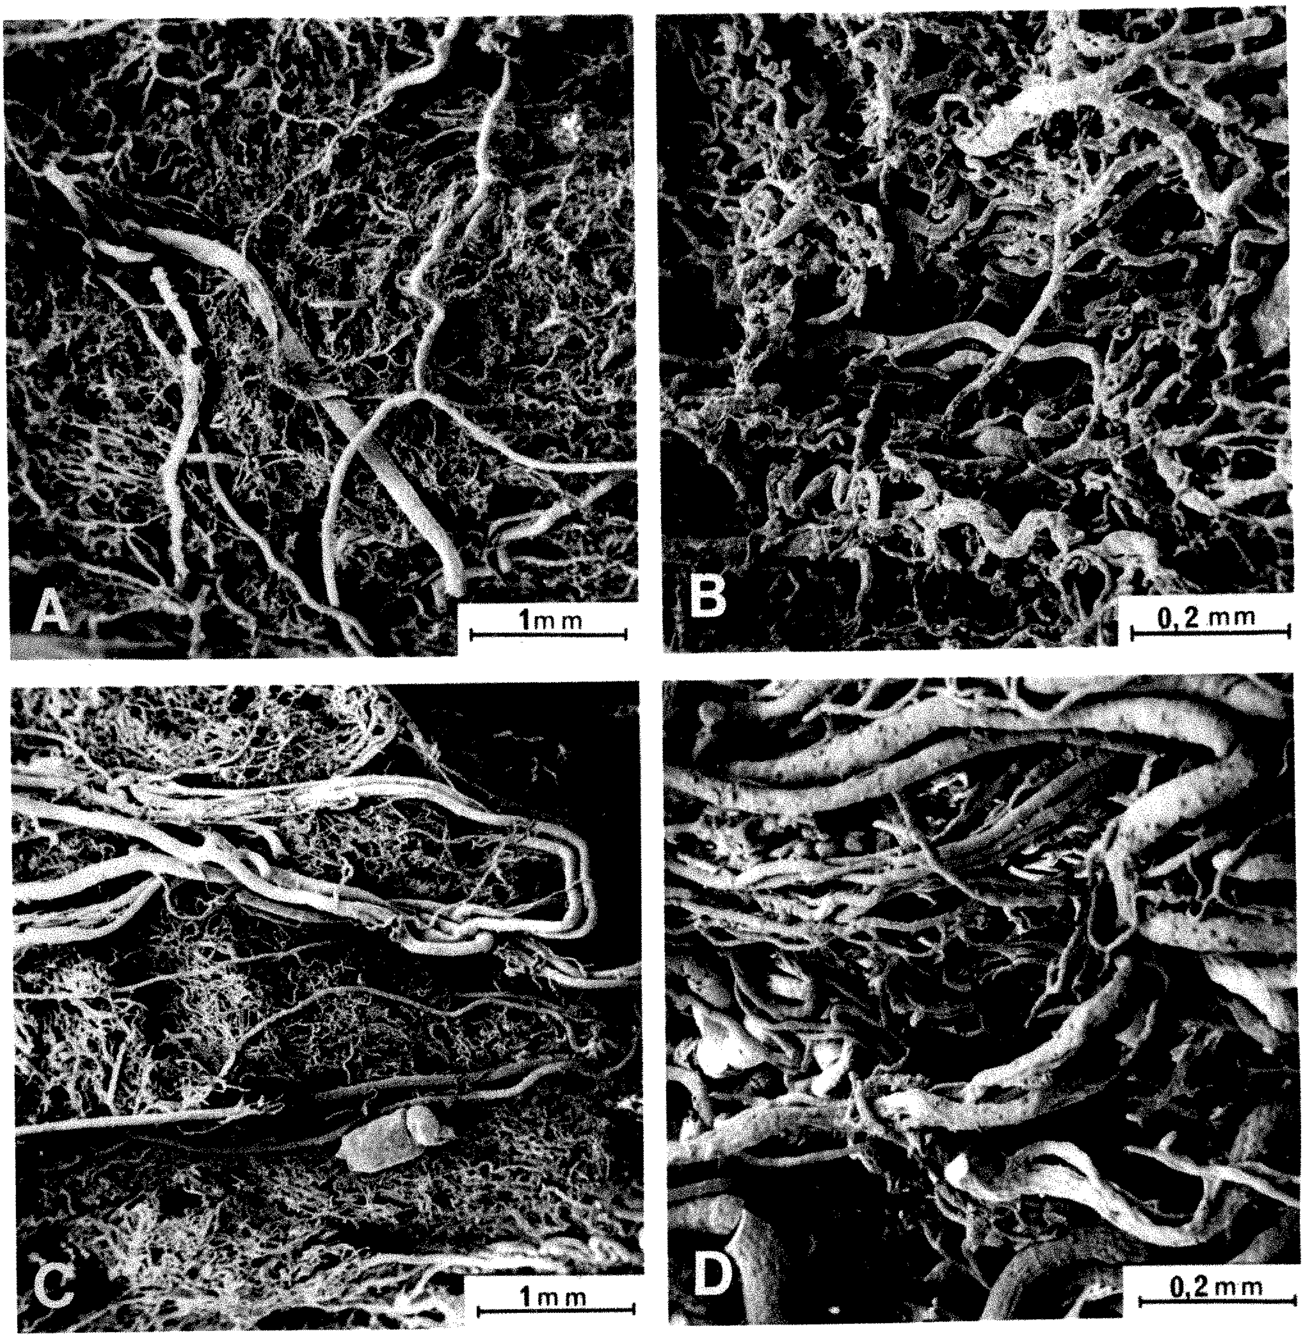

FIGS. 5A–D. Microvasculature of the esophagus. Mercox specimen. Scanning electron microscopy of complete vascular casts with arterioles, capillaries, and veins. *A* and *B*. 7-cm cranial of the cardia. *C* and *D*. at the cardia. Submucosal network at different magnifications viewed from the external aspect. The vessels form a polygonal meshwork overlying the mucosa (SEM by Dr. Düggelin, Basel).

ranged from 2.3–1.5 mm close to its aortic origin, all were divided and less than 1 mm at entering the esophageal wall (0.8–0.3 mm).

In 10 of the 16 specimens, complete rows of intercostal arteries with stumps of at least 1–4 cm in length were obtained. Only two of these had one small arterial branch to the esophagus, both arising from the fourth right intercostal artery.

Intra-abdominal Esophagus

The lower esophagus and the cardia were supplied by up to 11 larger caliber branches of 0.5–2 mm diameter originating from the left gastric artery (Figs. 3 and 8). Some of these arose close to the origin of the left gastric artery, and ran 2–3 cm alongside the right lateral aspect of the cardia before dividing into smaller branches.

These branches supplied the right lateral and anterior wall but only parts of the dorsal cardia and lower esophagus. The dorsal aspect of the cardia and lower esophagus was supplied by branches of the splenic artery *via* larger caliber fundal branches and numerous small fundal tributories. The left gastric artery and the splenic artery arose at variable location from the celiac axis (Fig. 9). A great variability was also seen with the origin of the inferior phrenic arteries (Fig. 10). These occasionally arose close to the left gastric artery; however, we never found any branch supplying the esophagus. Figure 11 summarizes the general pattern of the stem arteries and the vascular orientation in the esophagus.

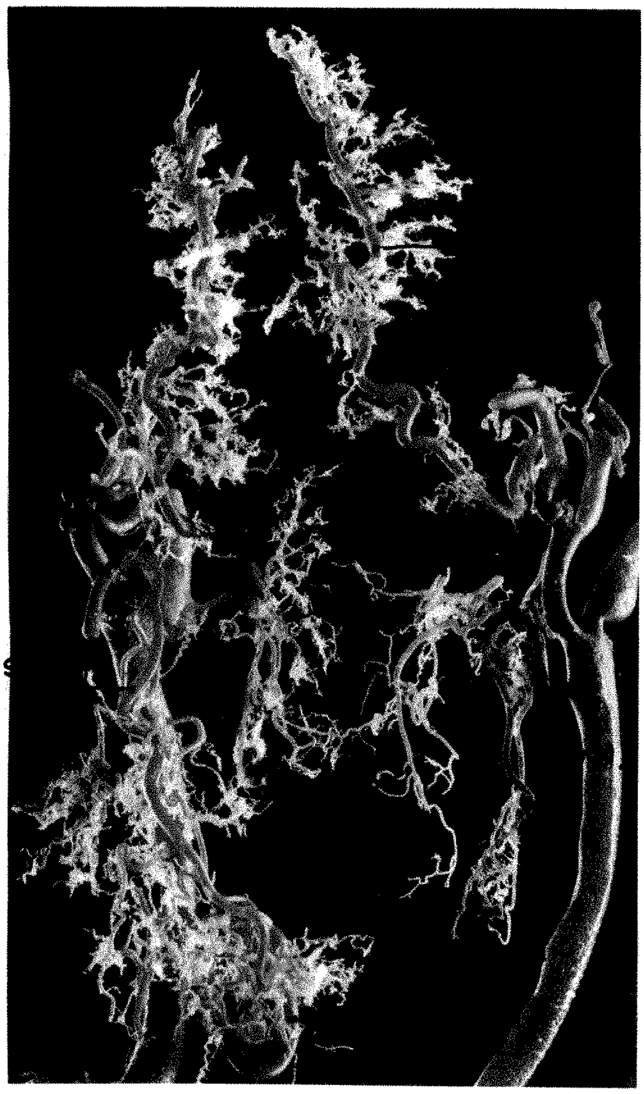

FIG. 6. Arterial cast of the cervical area and tongue with lingual artery (l.A.) from the anterior aspect. Beracryl specimen. The contours in the center show the esophageal arteries (e.A.) arising from the right and left superior thyroid arteries (S.th.A.) in this example. Both arose from the common thyroid artery (c.c.A.). The right branch of the superior thyroid artery descended and anastomosed with the right inferior thyroid artery (i.th.A.). This also gave off branches to the esophagus (e.A.).

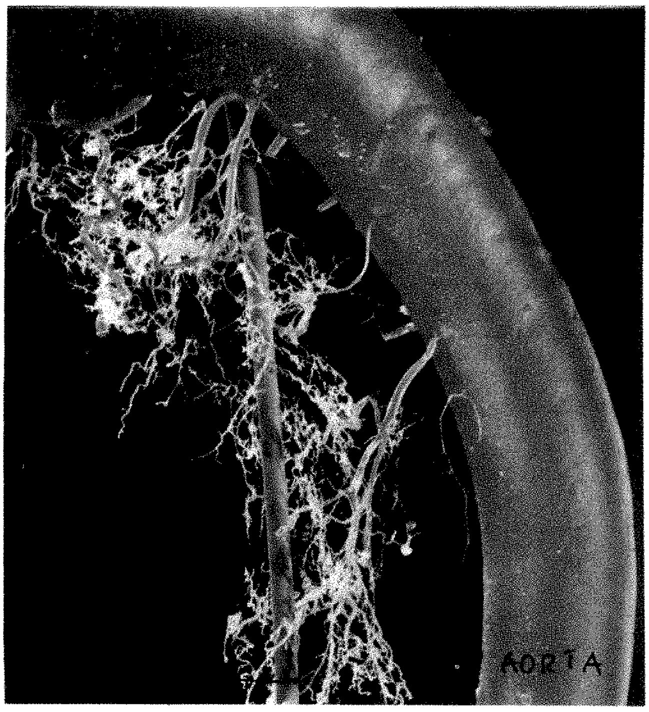

FIG. 7. Arterial cast (Beracryl) showing the bunch of tracheobronchial arteries. These arise from the aortic arch and give off multiple, very small branches (100–300 μm) to the esophagus. A catheter is still in place in the esophageal lumen. Left dorsolateral aspect.

Discussion

The rich but delicate vascularization of the esophagus is of concern in all surgery of this organ. There are, however, only a few original studies on the intimate vascular supply of the esophageal wall in humans. Some reports do not clearly indicate whether they relate to the human or the dog.

The three-dimensional display obtained with corrosion casts provided a reliable view of the arterial system. We took advantage of the two rather new, commercially available synthetic resins. Mercox crosses the capillaries and displays the complete arteriovenous network. Beracryl has a particle size of 150 μm and therefore limits its penetration to corresponding size arterioles without penetrating into the arteriolae retae and the venous side of the circulation. This eliminated time-consuming pruning. Shrinkage of the material was negligible. The vascular casts were moderately strong, rigid, and did not warp. Accurate and permanent mounting preserved the record.

The wide distribution of Beracryl with complete arterial architecture of the intestines suggested that firstly the interruption and secondly the poorer display of the arterial tree of the intrathoracic esophagus was not due to technical failure but to the small diameter of the periesophageal vessels. Injection with Mercox with its ex-

FIG. 8. Diagram of the most common distribution of the arterial stem vessels and branches that supply the intrathoracic and abdominal esophagus in one of the specimens. Right lateral aspect with aorta untwisted. The arterial diameter is approximately in scale. The preferable site of surgical ligation of the left gastric artery is shown with an arrow. This retains some arterial supply to the esophagus.

tremely low viscosity documented that the esophageal branches were connected by a dense network of minute vessels located in the submucosa and mucosa. The evident continuity of the vessels and the rich anastomosing intramural vascularity explains why the mobilized esophagus retains an "excellent blood supply" over a long distance,[30] and why ligation of the left gastric artery most of the time does not compromise the surgical anastomosis. The extremely small caliber of the nutritional vessels, on the other hand, may also explain the failure of esophagointestinal anastomosis in case of any mechanical damage or disturbance of the microvascular circulation.

With respect to the upper third of the esophagus, we confirmed previous work[39–41] demonstrating rich supply from all of the thyroid arteries. Our main interest centered on the intrathoracic arterial supply. Our results explain the apparent paradox of relatively important arterial branches supplying the medial third of the esophagus leading to surprisingly moderate bleeding on blunt dissection. This paradox is explained by the fact that these arteries branch off into minute vessels in the periesophageal mediastinum before entering the esophageal wall. If, however, the tumor involves related structures, fatal bleeding from the azygos vein,[9,15,29] tracheal tear and pneumothorax,[5–7,15,31–33] and lesions of the recurrent nerve may occur.

With regard to the abdominal blood supply, branches of the left gastric artery as a third main source supplied both the lower intrathoracic and intra-abdominal esophagus and the cardia. In addition, we found that the posterior aspect of this area received an excellent blood supply from fundal branches or direct branches of the splenic artery.

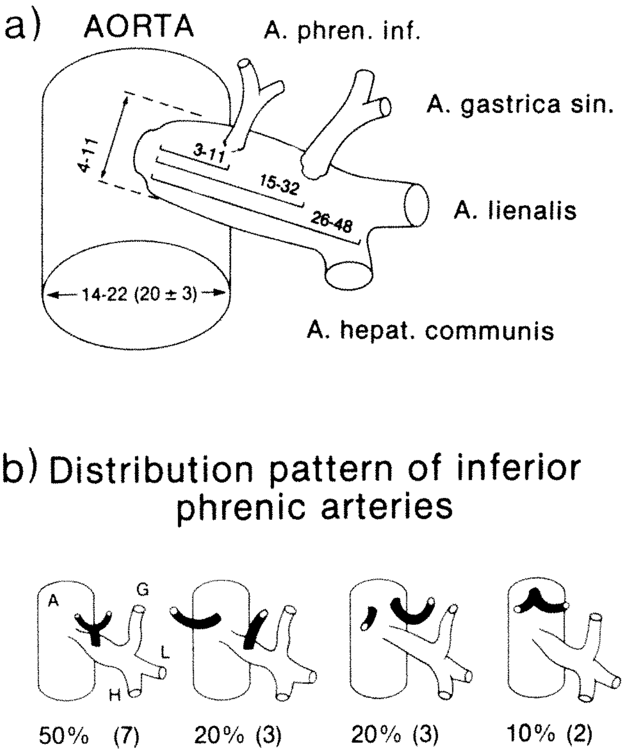

FIG. 9. Diagram of the celiac axis and its branches. a) The first branch was the inferior phrenic artery (A. phren. inf.) in 70%; second branch was the left gastric artery (A. gastrica sin.) in 100%. Finally, the celiac axis divided into the splenic artery (A. lienalis) and the common hepatic artery (A. hepat. communis). The site of arterial branching is given as range distance in millimeters from the origin of the celiac axis. b) The site of origin of the inferior phrenic arteries and their distribution in our specimens is shown. These vessels supplied only the diaphragm: none of our specimens had branches to the esophagus. A = artery, G = left gastric artery, L = splenic artery, H = common hepatic artery.

Branches from the right fourth and fifth intercostal arteries have been described in 25% of the cases.[19,21,22] In 10 specimens we found two small vessels from the fourth intercostal arteries, both of them supplying the tracheobronchial area giving off only minute branches, if any, to the esophagus. An extensive supply from many intercostal arteries, as often shown in textbooks, is true for the dog's esophagus[34-37] as we could confirm in four dogs with our technique, but not in humans.

Our findings also correct the unsubstantiated claim that caudal phrenic arteries play a role in esophageal vascularization.[19,22] In some of the specimens we found the origin of both phrenic and gastric arteries from the celiac axis being extremely close: larger caliber esophageal branches from the left gastric artery may have been erroneously taken for a phrenic artery in similar cases.

In conclusion, two points may be stressed on the basis of our findings: (1) The moderate bleeding observed after blunt esophagectomy is due to the fact that the nutritional arteries divide into minute branches within the periesophageal mediastinal tissue before entering the esophageal wall. The physiologic response of these small vessels to tearing is post-traumatic contracture with secondary thrombosis, hence hemostasis. (2) There are long segments of the esophagus supplied by dense vascular networks within the esophageal wall connecting the various vascular territories. They can compensate for the severance of one of the vascular sources. Rough manipulation of the organ may, however, easily compromise this intramural vascular network, thus jeopardizing surgical anastomosis with the stomach or gut regardless of the techniques applied.

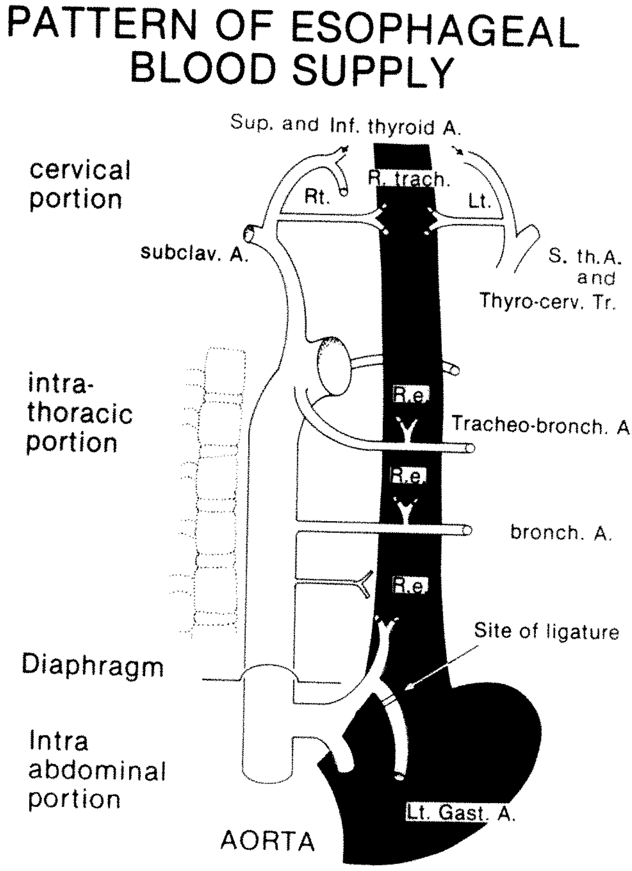

FIG. 10. This scheme summarizes the most common extraparietal sources of esophageal blood supply (stem vessels) and their topographical relations. All the esophageal branches (R.e.) arising from the stem vessels were extremely fine (100–500 μm). A = artery, Tr = trunc, Lt = left, Rt = right. The preferable site of surgical ligation of the left gastric artery is shown with an arrow.

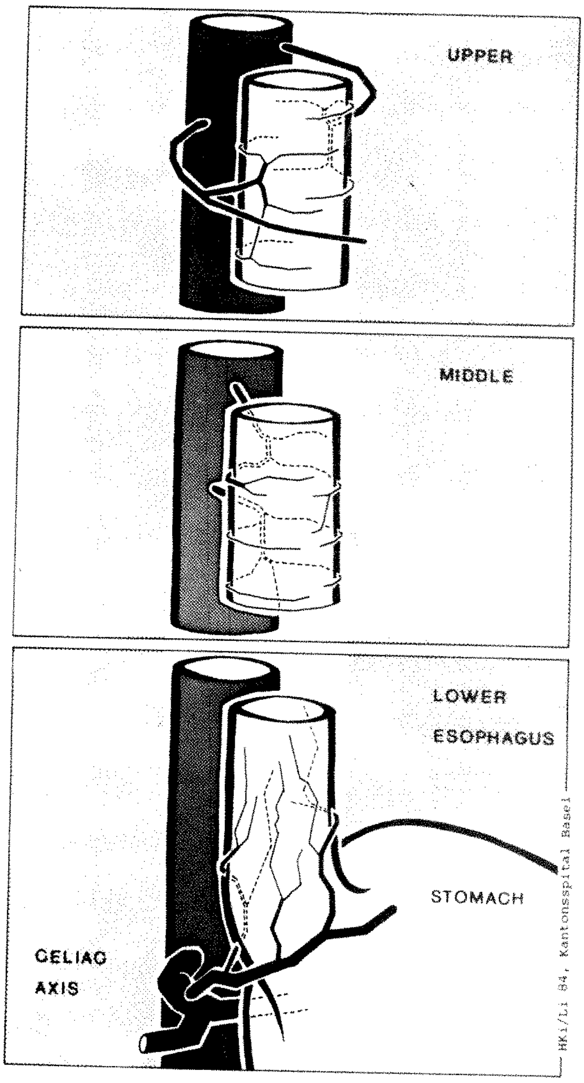

FIG. 11. Schematical representation of the vascular orientation. Smaller arteries run mainly horizontal in the upper esophagus and vertical to the axis in the lower esophagus. These arteries were complemented by the microvascular network that connected the arteries in the submucosa throughout the esophagus.

Our study does not allow any statement with regard to "oncological adequacy" of the blunt esophagectomy. Careful evaluation of this procedure for tumors restricted to the esophageal wall would seem worthwhile. It appears of particular interest in all patients having significant pulmonary disease.

Acknowledgments

We thank Professor Dr. R. Guggenheim and Dr. Düggelin, Institut für Rasterelektronenmikroskopie, Universität Basel, Switzerland, for their help with evaluation of the microcirculation. We also thank Professor Dr. Heitz and collegues of the Institute of Pathology for the autopsy material.

INTERNATIONAL SYMPOSIUM ON SARCOMAS
AT INNISBROOK, TARPON SPRINGS, FLORIDA
OCTOBER 8-10, 1987

Program Chairman: James R. Ryan, M.D.
Intergroup Sarcoma Committee

The first international symposium, to date, involving all of the disciplines treating sarcomas, this is a planned interdisciplinary program including orthopaedic surgeons, general surgeons, medical oncologists, pediatric oncologists, radiation oncologists and pathologists. The program is designed as didactic lectures followed by panel discussions to stimulate educational debate as to the different forms of treatment for sarcomas.

NAUSEA AND VOMITING CAN RUIN YOUR BEST WORK.

SURGICAL PERFECTION DEMANDS A POSTOPERATIVE ANALGESIC WITH FEW IMPERFECTIONS

STADOL® (butorphanol tartrate) lets you be as demanding about pain management as you are about surgical technique. Because STADOL provides the same relief as morphine and meperidine, but usually without the nausea and vomiting that requires an antiemetic... or a return to the OR.

You can dose STADOL based on patient need — rather than narcotic shortcomings — because it has a ceiling effect on respiratory depression and a low addiction potential. And even the sedation that may occur is different: the patient remains cooperative and responsive. Do not use STADOL when there's evidence of narcotic abuse or addiction as it may cause withdrawal. But for most cases STADOL can help smooth the patient's full recovery. Which, after all, is every surgeon's best work.

Please see next page for brief summary of prescribing information.

Stadol® IM IV

(butorphanol tartrate)

NO PAIN. FEWER PROBLEMS.

BRISTOL®

Stadol® (butorphanol tartrate)
Brief Summary of Prescribing Information
For complete information, consult Official Package Circular.

INDICATIONS AND USAGE–Stadol is recommended for the relief of moderate to severe pain. Stadol can also be used for preoperative or preanesthetic medication, as a supplement to balanced anesthesia, and for the relief of prepartum pain.

CONTRAINDICATIONS–Stadol should not be administered to patients who have been shown to be hypersensitive to it.

WARNINGS–Patients Physically Dependent on Narcotics: Because of its antagonist properties, Stadol is not recommended for patients physically dependent on narcotics. Detoxification in such patients is required prior to use.

Due to the difficulty in assessing addiction in patients who have recently received substantial amounts of narcotic medication, caution should be used in the administration of Stadol. Detoxification of such patients prior to usage should be carefully considered.

Use During Balanced Anesthesia: Since the combined respiratory depressant effect of all intravenous medication used during conduct of general anesthesia may lead to underventilation or apnea, butorphanol should be administered during balanced anesthesia only by persons specifically trained in the use of intravenous anesthetics and adjuncts, the maintenance of a patent airway and management of respiratory effects of all intravenous medication administered. An opioid antagonist, resuscitative and intubation equipment and oxygen should be readily available.

Drug Dependence: Special care should be exercised in administering Stadol to emotionally unstable patients and to those with a history of drug misuse. When long term therapy is contemplated, such patients should be closely supervised. Even though Stadol has a low physical dependence liability, care should be taken that individuals who may be prone to drug abuse are closely supervised. It is important to avoid increases in dose and frequency of injections by the patient and to prevent the use of the drug in anticipation of pain rather than for the relief of pain.

Head Injury and Increased Intracranial Pressure: Although there is no clinical experience in patients with head injury, it can be assumed that Stadol, like other potent analgesics, elevates cerebrospinal fluid pressure. Therefore the use of Stadol in cases of head injury can produce effects (e.g., miosis) which may obscure the clinical course of patients with head injuries. In such patients Stadol must be used with extreme caution and only if its use is deemed essential.

Cardiovascular Effects: Because Stadol increases the work of the heart, especially the pulmonary circuit, (see Clinical Pharmacology), the use of this drug in acute myocardial infarction or in cardiac patients with ventricular dysfunction or coronary insufficiency should be limited to those who are hypersensitive to morphine sulfate or meperidine.

PRECAUTIONS–Certain Respiratory Conditions: Because Stadol causes some respiratory depression, it should be administered only with caution and low dosage to patients with respiratory depression (e.g., from other medication, uremia, or severe infection), severely limited respiratory reserve, bronchial asthma, obstructive respiratory conditions, or cyanosis.

Impaired Renal or Hepatic Function: Although laboratory tests have not indicated that Stadol causes or increases renal or hepatic impairment, the drug should be administered with caution to patients with such impairment. Extensive liver disease may predispose to greater side effects and greater activity from the usual clinical dose, possibly the result of decreased metabolism of the drug by the liver.

Biliary Surgery: Clinical studies have not been done to establish the safety of Stadol administration to patients about to undergo surgery of the biliary tract.

Usage as a Pre-operative or Pre-anesthetic Medication: Slight increases in systolic blood pressure may occur, therefore caution should be employed when Stadol is used in the hypertensive patient.

Usage in Pregnancy: The safety of Stadol for use in pregnancy prior to the labor period has not been established; therefore, this drug should be used in pregnant patients only when in the judgment of the physician its use is deemed essential to the welfare of the patient.

Reproduction studies have been performed in rats, mice, and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to Stadol at about 2.5 to 5 times the human dose.

Usage in Labor and Delivery: Safety to the mother and fetus following the administration of Stadol during labor has been established. Patients receiving Stadol during labor have experienced no adverse effects other than those observed with commonly used analgesics. Stadol should be used with caution in women delivering premature infants.

Usage in Nursing Mothers: The use of Stadol in lactating mothers who are nursing their infants is not recommended, since it is not known whether this drug is excreted in milk. Stadol has been used safely for labor pain in mothers who subsequently nursed their infants.

Usage in Children: Safety and efficacy in children below age 18 years have not been established at present.

ADVERSE REACTIONS–The most frequent adverse reactions in 1250 patients treated with Stadol are: sedation (503, 40%), nausea (82, 6%), clammy/sweating (76, 6%).

Less frequent reactions are: headache (35, 3%), vertigo (33, 3%), floating feeling (33, 3%), dizziness (23, 2%), lethargy (19, 2%), confusion (15, 1%), lightheadedness (12, 1%).

Other adverse reactions which may occur (reported incidence of less than 1%) are:

CNS: nervousness, unusual dreams, agitation, euphoria, hallucinations, seizures
Autonomic: flushing and warmth, dry mouth, sensitivity to cold
Cardiovascular: palpitation, increase or decrease of blood pressure
Gastrointestinal: vomiting
Respiratory: slowing of respiration, shallow breathing
Dermatological: rash or hives
Eye: diplopia or blurred vision

OVERDOSAGE–Manifestations: Although there have been no experiences of overdosage with Stadol during clinical trials, this may occur due to accidental or intentional misuse as well as therapeutic use. Based on the pharmacology of Stadol, overdosage could produce some degree of respiratory depression and variable cardiovascular and central nervous system effects.

Treatment: The immediate treatment of suspected Stadol overdosage is intravenous naloxone. The respiratory and cardiac status of the patient should be evaluated constantly and appropriate supportive measures instituted, such as oxygen, intravenous fluids, vasopressors and assisted or controlled respiration.

SUPPLY–Stadol (butorphanol tartrate) Injection for I.M. or I.V. use is available as follows:

NDC 0015-5644-20–2 mg per ml, 2-ml vial
NDC 0015-5645-20–1 mg per ml, 1-ml vial
NDC 0015-5646-20–2 mg per ml, 1-ml vial
NDC 0015-5648-20–2 mg per ml, 10-ml multi-dose vial

For information on package sizes available, refer to the current price schedule.

High-dose Photoirradiation of Esophageal Cancer

ROBERT J. THOMAS, F.R.A.C.S.,† MARGARET ABBOTT, R.N.,* PRITHI S. BHATHAL, PH.D., F.R.C.P.A.,‡
D. JAMES B. ST. JOHN, F.R.A.C.P.,§ and GEORGE MORSTYN, PH.D., F.R.A.C.P.*†

Fifteen patients with locally advanced esophageal cancer were treated with phototherapy. Each patient had dysphagia and weight loss before therapy and could not be operated on because of the extent of the tumor or poor performance status. Patients received a photosensitizer (hematoporphyrin derivative) 72 hours before phototherapy and were then treated by light delivered by an argon pumped dye laser or gold metal vapor laser at powers up to 2.2 W and doses of 337 J/cm^2. Fourteen patients received 24 treatments. The results were *all* patients achieved a tumor response. The depth of response depended on the dose and dose rate of radiation. There were four of 24 local complications (mediastinitis 3, bronchoesophageal fistula 1). These occurred in patients treated with a power of greater than 1.5 W. There were two complete pathologic remissions in patients with locally advanced cancer. In conclusion, phototherapy is an effective alternative to other forms of palliation and potentially may be an alternative to surgery in selected cases of locally advanced esophageal cancer.

TREATMENT OF CARCINOMA of the esophagus is unsatisfactory. Although there has been recent improvement in the survival of patients treated by surgical resection,[1] the survival of patients with inoperable cancer is poor. Furthermore, radiotherapy, chemotherapy, or dilation and intubation often do not provide good palliation. There have been several reports on the use of laser therapy for the creation of a larger esophageal lumen to enable patients to swallow. This has been achieved either by directly coagulating tumor with an Nd Yag Laser or by photodynamic therapy using an argon pumped dye laser emitting light of 630 nm onto tumors presensitized with hematoporphyrin derivative (HpD).[2-9]

From the Melbourne Tumour Biology Branch, Ludwig Institute for Cancer Research, Department of Surgery,† Department of Anatomical Pathology,‡ and Department of Gastroenterology,§ PO Royal Melbourne Hospital, Victoria, Australia*

HpD has been shown to selectively localize in many human and experimental tumors[4] and to sensitize them to kill by light of appropriate wavelength. Photodynamic therapy has been used to treat many human tumors, including recurrent breast cancer,[4] squamous carcinoma of the head and neck,[5] bronchial carcinoma,[6] gastrointestinal tract cancer,[7] and bladder cancer.[8] Complete and partial response rates of up to 60% have been reported in bronchial and gastrointestinal tract cancers. There have been two previous reports dealing specifically with esophageal cancer. McCaughan et al.[9] reported the results of 16 patients with advanced cancer and Hayata et al.[7] reported on the results of 12 patients with advanced cancer.

These studies have not attempted to identify the maximum tolerable dose of light for the phototherapy of esophageal cancer. Variable dose rates were used with powers of 90–400 mW and 200–1000 mW.[7,9] It is not clear whether dose rate is an important determinant of tumor kill, although it is clearly important for the kill produced by x-irradiation.[10] The dose of light delivered in one of the studies[7] was less than 150 J/cm^2; in the other study[9] insufficient information was provided to calculate the dose delivered.

The dosimetry in photodynamic therapy is poorly developed. Only the power output of the laser and the duration of therapy can be measured accurately. The surface area of the tumor can only be estimated and the delivery systems using fibers with a variety of tips provide variable distribution to the tumor. The absorbed dose of light cannot be measured. We describe a method

SCC = squamous cell carcinoma. ECOG = Eastern Clinical Oncology Group.

of applying light to an esophageal cancer that improves the accuracy of light delivery using a balloon filled with a light dispersing medium. We have undertaken a Phase 1 study of photodynamic therapy of advanced esophageal cancer using an argon pumped dye laser and a gold metal vapor laser. We have used high power levels up to 2.2 W and large doses up to 337 J/cm^2 to determine doses of light that are tolerable and whether the extent of tumor kill is dose related.

Patients and Methods

All patients gave informed consent before the study. Fourteen patients were admitted to the Phase 1 study. They were treated from March 1985 to September 1986. In the first half of the study patients were assessed as being unsuitable for any other form of therapy. In the second half of the study, photodynamic therapy was offered as an alternative to other forms of palliative therapy. The characteristics of the patients and tumor types are shown in Table 1. This study was approved by the Ethics Committee of the Royal Melbourne Hospital.

Technique of Photodynamic Therapy

An intravenous infusion of 2.5–5.0 mg/kg of HpD was administered to all patients 72 hours before laser therapy. HpD was obtained from the Pharmacy Department of Queen Elizabeth Hospital (Adelaide, South Australia) and was prepared by the acetylation of hematoporphyrin using the method described by Forbes et al.[11]

Hematologic and biochemical parameters were measured regularly after the infusion to assess and detect any toxic effects of the HpD. In five patients fluorescence was measured in the serum to assess peak levels and decay characteristics. Patients were screened from direct sunlight for up to 1 month. Laser light at 627–630 nm was generated using an argon pumped Rhodamine B dye laser (Spectra Physics, Model 164-05; argon laser, Model 375 dye laser, Spectra Physics, Mountain View, CA (9 patients, 16 therapies) or a gold metal vapor laser (Quentron, South Australia) (8 patients, 8 therapies). Light was delivered through a quartz fiber with a power output at the fiber tip varying from 0.5–2.2 W.

The quartz fiber was passed down a flexible endoscope (Olympus GIFQ, Olympus Optical Co., Ltd., Japan) and light directed towards the tumor. Eye protection was worn by the operator during this procedure.

To control the dose of light applied to the tumor, a light delivery system was devised as shown in Figure 1. This consisted of a polythene cannula with an attached thin-walled balloon that assumed an elongated shape measuring 8 × 1 cm in diameter when distended with 0.5% lipid emulsion (Intralipid®). The balloon was introduced into the lumen of the esophageal cancer *via* the fiberoptic endoscope after dilation of the cancer. With the balloon accurately in place within the tumor, the quartz fiber was moved from one end of the balloon to

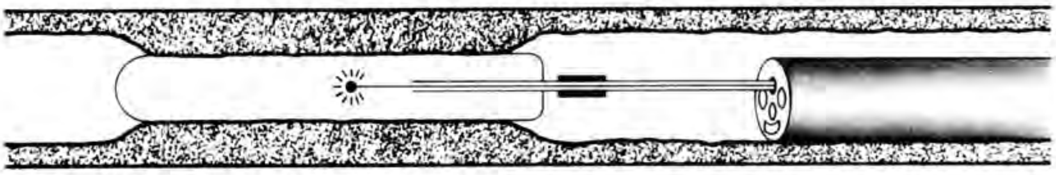

FIG. 1. Schema of delivering light to the tumor. The diagram shows the laser fiber in a balloon filled with Intralipid (0.5%) in the lumen of the esophagus.

the other within the esophageal cancer resulting in light delivery to the whole tumor. The dosimetry was calculated assuming that the tumor was a cylinder with a diameter of 1 cm after the balloon was inflated within the lumen of the tumor. The length was determined by prior endoscopy. Doses of light between 60 and 337 J/cm^2 of tumor were delivered. This necessitated treatment times of 30–60 minutes. All patients in this series were treated under general anesthesia.

Assessment of Tumor Response

Before the laser therapy all the patients had endoscopic examination, the tumors were biopsied, photographed, and dilated if necessary, and the length of the tumor was measured. Barium meal and computed tomographic (CT) examinations of the thorax were obtained before treatment and 1 month after treatment. After laser therapy all patients had endoscopic examination at 48 hours and further photographs and biopsies were taken. This procedure was repeated 1 week and 2 weeks after therapy and when new symptoms such as dysphagia developed.

Results

The characteristics of the patients with esophageal cancer are shown in Table 1. Of the 14 patients, five had an adenocarcinoma and nine had a squamous cell carcinoma. Seven patients had lower-third tumors, six had mid-third tumors, and one had an upper-third tumor. Six patients had previous treatment, either radiotherapy or surgery. Twelve patients had advanced local mediastinal spread, and two patients had disease apparently confined to the esophagus on CT scan. All patients were deemed inoperable due to their clinical status or the stage of their tumor.

The details and results of the laser therapy are shown in Table 2. A total of 24 laser therapies were given to the

14 patients. In seven treatments, HpD was given at a dose of 2.5 mg/kg; in an additional 17 treatments, HpD was given at a dose of 5 mg/kg.

The gold metal vapor laser was used in eight of the 24 laser treatments. The mean power output at the fiber tip with this laser was 1.8 W (range: 1.7–2.2). The mean power output at the fiber tip of the argon pumped dye laser was 1.0 W (range: 0.5–2.0). The mean total dose of light was 3582 J (range: 1800–6039). The mean dose/cm^2 of tumor was 168 J/cm^2 (range: 60–337).

The degree of necrosis of the cancer after laser therapy was estimated by visual grading of the macroscopic appearance of the tumor at the postlaser endoscopic examinations. The necrosis was graded as follows: G0: no tumor necrosis visible; G1: tumor necrosis but obvious viable tumor persisting (Fig. 2); G2: apparent total tumor necrosis (Fig. 3); G3: total tumor necrosis with a physical appearance of esophageal tumor slough (Fig. 4).

The relationship between tumor necrosis (G_0–G_3) and light dose and power output of the laser is shown in Figure 5. G_1 minimal tumor necrosis correlated significantly with the dose of light (Spearman rank correlation test, correlation coefficient 0.368, $p = 0.04$) G3 esophageal tumor slough correlates significantly with a power output of the laser of >1.5 W (Spearman rank correlation test, correlation coefficient 0.54, $p = 0.005$).

The palliation of the symptoms produced by the tumors was assessed by measuring the improvement of dysphagia after therapy (Table 2).

The ability to swallow was assessed before laser therapy and 2 weeks after laser therapy using a dysphagia scale, and all patients achieved measurable improvement in the severity of dysphagia. The duration of the response varied from 1 to 28 weeks with a median of 9.5 weeks. With respect to weight changes, seven of the 14 patients maintained their weight from the time of laser therapy to 1 month after the therapy despite a history of loss of weight in the 3 months before treatment. The remainder of the surviving patients showed modest declines in weight.

The in-hospital mortality rate was 14% with two patients dying after their therapy, both aged over 80 years. One of these patients was shown at postmortem examination to have complete necrosis of the esophageal cancer but also significant esophageal wall necrosis associated with thrombosis of an esophageal artery (Fig. 6). In this instance cardiac arrest occurred 13 days after therapy and the postmortem examination showed significant coronary artery disease. The second patient in whom bronchoesophageal fistula pneumonia developed died 4 weeks after the therapy, and at postmortem examination had an extensive esophageal and mediastinal tumor with massive necrosis of the esophageal portion of the tumor.

Survival Data

A number of complications occurred after the therapy and are listed in Table 2. Febrile episodes were common but settled with the institution of antibiotics. In one patient mediastinitis developed with pleural effusions demonstrated on CT scan. This patient was treated conservatively with full recovery and subsequently had a strictured area of the esophagus resected (8 months after laser treatment). Histologic examination of the specimen revealed complete eradication of the esophageal tumor with a dense fibrous scar formation. There has been no recurrence of tumor 1 year later. This patient had heavy irradiation to the neck and esophagus for a paraesophageal tumor 10 years before the development of the presumed radiation-induced proximal esophageal cancer.

A laser power output of >1.5 W correlated significantly with the development of complications.

All patients received instructions to avoid direct sun. However, three patients showed a reaction to sunlight when inadvertently exposed. In two of these patients, their skin reaction developed in the hospital from light coming through the windows. In another patient, sun sensitivity developed after leaving the hospital. It was evident that this phenomenon of sun sensitivity persisted for several months after the therapy, and in one patient skin pigmentation developed that persisted for more than 6 months before fading. The basis for prolonged skin sensitivity is not clear. However, Figure 7 shows that HpD fluorescence can persist in the serum for up to 1 month. Similar findings were found in four other patients. There was no effect of HpD on liver or renal function as measured biochemically. To determine the effect of phototherapy on survival we compared the actuarial survival of all 14 patients with a previous series of patients treated for palliation nonsurgically (Fig. 8).[1] This survival has been stable in the hospital for 5 years. There was no significant difference between the curves.

Discussion

This study confirms that photodynamic therapy is an effective form of local therapy for esophageal cancer. All tumors treated showed some evidence of necrosis. In this group of patients there was no apparent difference in the response of squamous and adenocarcinomas.

This form of therapy produced reasonable palliation in patients who were close to having or had complete obstruction. The degree of palliation appeared to be at least as good as that produced by other forms of therapy. The eventual place for photodynamic therapy as a palliative treatment of advanced esophageal cancer is still to be established. It is likely that certain groups of pa-

tients will be better treated with this form of therapy than others. Further studies are needed to compare the various methods of palliation.

Of particular interest is the ability of photoirradiation therapy to produce complete eradication of local tumors. There are reports in the literature of the complete eradication of early esophageal and gastric cancers by photodynamic therapy.[6,7] This study includes the first cases of locally advanced esophageal cancer where local eradication of tumors has been obtained. Both patients had squamous carcinomas in the mid-esophagus with no prior therapy. One patient has had complete eradication proven by resection of a persisting stricture after the development of esophageal slough (grade G3). This patient had a locally advanced tumor on the basis of thickening in the mediastinum on CT scan but poor pulmonary function, and frailty initially precluded surgery. The patient received two treatments with the argon pumped dye laser with fairly rapid recurrence of the tumor. After a third treatment with the gold metal vapor laser mediastinitis developed and the patient required respiratory support for 5 days and drainage of pleural effusions. She recovered after this therapy but a persistent esophageal stricture developed that became difficult to dilate. There were problems with endoscoping this patient and it was elected to risk resection of the stricture. At the time of resection a benign stricture was discovered and histologic examination confirmed the complete absence of local tumor. The area in which the

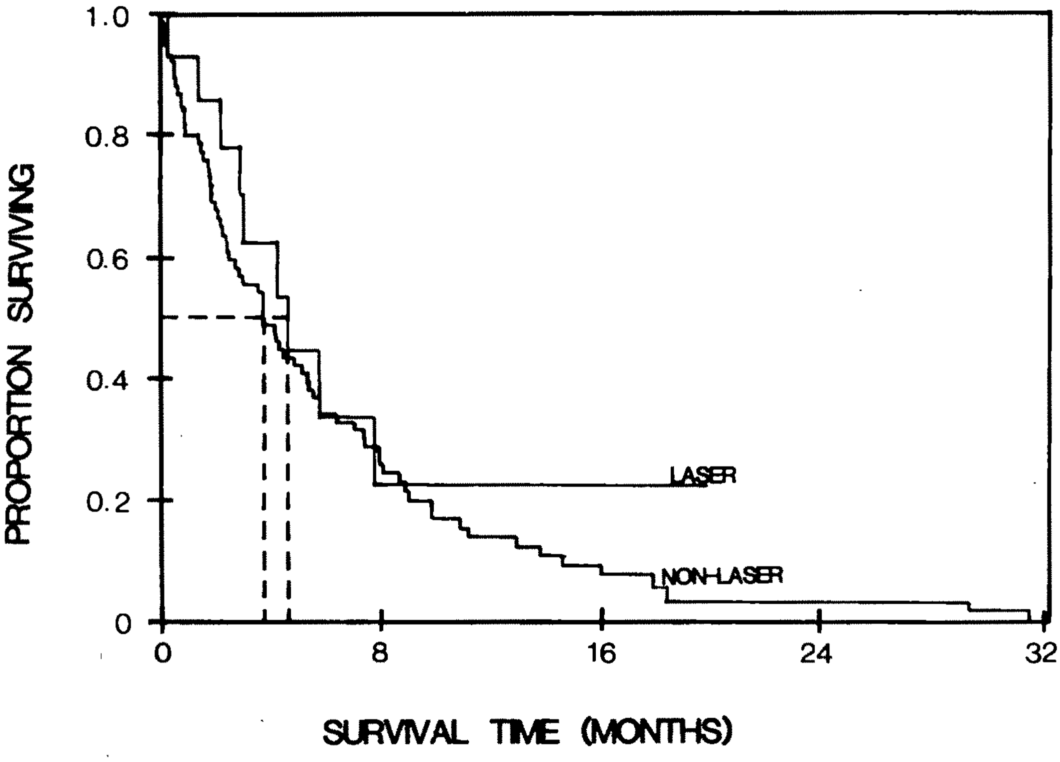

FIG. 8. Survival of all photoirradiation patients (laser) compared with patients treated for palliation before availability of photoirradiation.

tumor was previously noted was surrounded by a dense scar surmounted by a small shallow ulcer. This patient has remained tumor free for more than 12 months. The second instance where complete eradication was seen occurred in one patient who died 14 days after therapy and in whom at autopsy there was total necrosis of the tumor.

The ability to produce local eradication of advanced tumors raises the possibility of developing this form of therapy as a first-line form of treatment for Stage 1 esophageal cancer. However, increasing the effectiveness of the local therapy in this situation demands the development of techniques to support both the patient and the esophageal wall during the postoperative period when tumor necrosis is maximal and the repair processes have not developed sufficiently to maintain the integrity of the esophageal wall. Appropriate management may require antibiotics, nil by mouth, parenteral nutrition, and occasionally temporary intubation to splint the esophagus. This introduces a new dimension in the field of surgical oncology rather akin to the problems seen in the use of chemotherapy without surgery in lymphomas affecting the gastrointestinal tract to avoid perforation.

An important attribute of photodynamic therapy previously reported is the selectivity of cell damage. In this group of patients, however, it was evident that the selectivity was not absolute. There was generally a sharp demarkation between tumor necrosis and the proximal esophageal mucosa. However, in both the resected case and the autopsy specimen there was evidence of normal tissues deep to the tumor or close to the tumor showing necrosis. The histologic changes were characteristic after phototherapy with severe fibrinoid necrosis noted in blood vessels close to the tumor. This would suggest that a vascular phenomenon was significant in producing at least part of the necrosis. This may also be a factor in producing the damage to the normal esophageal wall. These vascular changes can resolve as was evident from the resected specimen of the eradicated cancer where recanalization of previously thrombosed vessels was seen. A vascular basis for the damage induced by phototherapy has previously been suggested based on *in vivo* experiments in small animals.[12]

A major problem with the assessment of the effectiveness of photodynamic therapy relates to the difficulties with dosimetry. Although the balloon system as described improves light delivery to the tumor, there may still be variation in the dose of light delivered to various parts of the tumor and the problem of a geographic miss also exists. This lack of precision makes it difficult to define the optimal doses of light for various tumors. In this study substantial variations in the dosage of light to the various areas of the tumor may have been responsible for variations in necrosis in various parts of the tumor. However a direct dose-response relationship was demonstrated in this study by comparing very low doses with higher doses of light. Extent of tumor necrosis also correlated with the presence of significant complications and occurred where the pulsed laser was used with a power output of greater than 1.5 W. There is an obvious need to clarify the problem of dose response. Our data suggest that for the therapy of esophageal cancers, lasers with a higher power may not be necessary since a limit determined by normal tissue tolerance may have been reached.

There is no systemic toxicity from phototherapy apart from the problem of sun sensitivity. This was found to be a persistent problem extending for 2–3 months from the time of laser therapy, and in some patients was associated with mild skin pigmentation. The development of photosensitizers with a shorter half-life would reduce this problem.

Blunt Thoracic Trauma

Analysis of 515 Patients

ROBERT M. SHORR, M.D., MICHAEL CRITTENDEN, M.D., MATTHEW INDECK, M.D.,
SUSAN L. HARTUNIAN, M.D., and AURELIO RODRIGUEZ, M.D.

A retrospective analysis of 515 cases of blunt chest trauma is presented. The overall thoracic morbidity rate was 36% and mortality rate was 15.5%. Atelectasis was the most common complication. Severe chest trauma can be present in the absence of rib or other thoracic bony fractures. Emergency thoracotomies for resuscitation of the patient with blunt chest trauma with absent vital signs proved unsuccessful in 39 of 39 patients. A high index of suspicion for blunt chest injury occurring in blunt trauma, coupled with an aggressive diagnostic and therapeutic approach, remains the cornerstone of treatment to minimize the morbidity and mortality of such injuries.

From the Maryland Institute for Emergency Medical Services Systems, Baltimore, Maryland

TRAUMA IS THE THIRD leading cause of death in the United States and the leading cause of death in persons under the age of 40. Twenty-five per cent of the 100,000 annual civilian traumatic deaths result from chest trauma.[1] Blunt thoracic injuries are more common than penetrating chest trauma, with the most frequent causes being motor vehicle accidents, falls, and crush injuries.[2]

The Shock Trauma Center of the Maryland Institute for Emergency Medical Services Systems (MIEMSS) is a 107-bed trauma referral center for the State of Maryland, serving a large population of patients with multisystem injuries, both acutely injured patients and traumatized patients referred from regional trauma centers. Seventy-five per cent of the admissions arrive by helicopter and 25% arrive by land transportation.

Between January 1982 and December 1984, 5378 patients were admitted to the MIEMSS Shock Trauma Center. We present a retrospective report on the MIEMSS experience with 515 patients who sustained blunt thoracic trauma within this 3-year period, including an analysis of the injury patterns, complications, and mortality for this group.

Materials and Methods

Five hundred fifteen patients were admitted to the MIEMSS Shock Trauma Center with blunt chest trauma between January 1982 and December 1984. The mean age was 36.9 years, with a range of 14–86 years. There were 374 males and 141 females admitted, constituting a male to female ratio of 2.7 to 1. The causes of these injuries encompassed automobile (70.9%), pedestrian (9.5%), and motorcycle accidents (7.8%); falls (7.6%); and miscellaneous causes (4.2%) (Table 1). Our miscellaneous category included injuries such as waterskiing accidents, assaults, farm accidents, a plane crash, and one person kicked by a horse.

Of the 515 patients, admission vital signs were available for 512 patients. Three hundred thirty-nine patients (66.2%) arrived with stable vital signs (defined as systolic blood pressure greater than 90 mmHg). One hundred forty-three patients (27.5%) had hypotension (defined as systolic blood pressure less than 90 mmHg). Thirty patients (5.7%) arrived with no pulse or blood pressure and with cardiopulmonary resuscitation in progress. The three patients whose admission vital signs were not available all died within 48 hours.

Results

The majority of patients with blunt chest trauma had an array of associated injuries. Although only 84 patients (16.3%) had isolated thoracic injuries, 431 patients (83.7%) had extrathoracic injuries. The magnitude of injury is further highlighted by the fact that nearly half (245) of these patients (47.5%) had two or more systems involved besides the thoracic injuries. The asso-

Submitted for publication: January 12, 1987.

ciated injuries included head trauma in 222 patients, extremity fractures in 205 patients, intra-abdominal injuries in 147 patients, and miscellaneous injuries in 181 patients. The miscellaneous category included spine injuries, pelvic fractures, facial trauma, and significant soft tissue injury.

Fractures of the Bony Thorax

Blunt thoracic trauma is often heralded by fractures of the bony thorax. These fractures reflect the large amount of energy that has been imparted to the chest wall and thoracic viscera (especially when the scapulae and sternum are involved). Recognition of these injuries is critical in the management of these patients. Rib fractures interfere with ventilation and may lacerate underlying lung parenchyma. Sternal and rib fractures may contribute to paradoxic chest wall motion and impair ventilation in that manner. If a scapula is fractured, high energy transfer has occurred to the thorax, and one must suspect that deeper structures have been injured.

Fractures comprised the largest single group of thoracic injuries in our series. There were 451 fractures of the ribs, scapulae, sternum, and clavicles either alone or in combination in 388 patients. Of these, rib fractures predominated (368), with nearly half of these involving three or more ribs. There was an 8% incidence of bilateral rib fractures. The remaining injuries comprised 14 sternal fractures, 43 clavicular fractures, and 25 scapular fractures. One hundred twenty-seven patients had no radiographic or clinical manifestations of bony thorax fractures despite the presence of other thoracic injuries.

Chest Injuries in the Absence of Fractures of the Bony Thorax

Bony fractures of the thorax (including ribs, clavicle, scapula, and sternum) are the most common injuries in blunt thoracic trauma and often are a hallmark of severe underlying injury. However, we have identified a group of patients with significant thoracic injuries in the absence of bony fractures. From our total group, we identified 127 (24.7%) such patients (Table 2); the majority of these injuries represented hemothoraces or pneumothoraces (62.2%). Nine of 19 ruptured thoracic aortas and 10 of 23 ruptured diaphragms were included in this group. Because the energy of forces is not dissipated by the fracturing of bones, other structures within the chest may become more vulnerable to injury. It is evident from this series that major thoracic blunt trauma cannot be ruled out in the absence of bony injuries.

Pneumothorax-Hemothorax

Pneumothorax is a frequent finding in blunt chest trauma. It is usually due to a rib fracture that is driven inward and damages the pulmonary parenchyma or to chest decelerating injuries, causing an abrupt increase in intra-alveolar pressure. Other causes of pneumothorax include a tear in the tracheobronchial tree or esophagus.[3]

TABLE 1. *Mechanism of Injury*

	No. of Patients	%
Automobile	365	70.9
Pedestrian	49	9.5
Motorcycle	40	7.8
Falls	39	7.6
Miscellaneous	22	4.2

Hemothorax often accompanies pneumothorax, with similar etiologies causing a tear in the blood vessels of the lung parenchyma, injury to intercostal vessels, or injury to the heart and great vessels.

Pneumomediastinum and pneumopericardium in the adult trauma patient are often incidental findings of air that has tracked along the bronchial or vascular sheaths of the thorax into the mediastinum and pericardium. Occasionally, this can be a grave sign of a ruptured bronchus or esophagus, uncontrolled pneumothorax, or ventilator barotrauma. Air within the pericardial space can develop into cardiac tamponade.[4]

In our series, 287 patients had complications of pneumothorax, hemothorax, or a combination of the two injuries. Of the 95 patients with pneumothoraces, 54 had simple pneumothoraces, 15 had bilateral pneumothoraces, eight had a tension pneumothorax, and one had an open pneumothorax. There were 17 patients in whom delayed pneumothoraces developed (defined as a pneumothorax occurring 24 hours after injury). Of the hemothorax group (193 patients), 54 patients had unilateral hemothoraces, 17 had bilateral hemothoraces, and 11 had delayed hemothoraces. One hundred eleven patients had various combinations of hemopneumothoraces.

In three of the six patients in whom pneumomediastinum developed, the condition was associated with car-

diac compromise due to tension pneumopericardium. Two patients had pneumomediastinum without pneumopericardium, and one patient had asymptomatic combination pneumomediastinum pneumopericardium.

Ruptured Diaphragm

Traumatic rupture of the diaphragm is a relatively rare finding in patients with blunt trauma. It is most commonly the result of motor vehicle accidents and is secondary to abrupt increases in intra-abdominal pressure. The injury usually occurs through the weakest points of the diaphragm, which are in the posterolateral positions along the embryonic fusion lines. However, diaphragmatic rupture has occurred in all areas of the diaphragm.[5] In previous series, right-sided diaphragmatic ruptures have been reported only rarely.[6] However, as this entity is more aggressively identified, right-sided lesions are being more frequently recognized.[7] Mortality is directly related to associated injuries.

We report on 23 cases of ruptured diaphragms: 16 (69.5%) were left sided and seven (30.5%) were right sided. Motor vehicle accidents were responsible for 78.0% of the injuries. Other causes included motorcycle accidents, pedestrian accidents, and a kick from a horse. In two cases (1 right and 1 left), diagnosis was delayed more than 1 week after injury. Of the patients with ruptured diaphragms, 14 (60.9%) had two or more systems involved, and the mortality rate was 26.9% (6 deaths). All injuries were repaired *via* abdominal incisions.

Aortic Ruptures

Traumatic thoracic aortic tears are one of the most catastrophic injuries seen in blunt chest trauma. The severity of such an event is appreciated when survival statistics are examined. A large, widely quoted study by Parmley has shown that only 20% of patients with aortic rupture survive for more than 1 hour after injury; 80% of patients die at the scene.[8] In initial survivors, if the injury is not surgically addressed, 40% die within 24 hours and 90% are dead by 10 weeks.

Nineteen patients presented to the MIEMSS Shock Trauma Center with a traumatic ruptured thoracic aorta; there were seven long-term survivors. As with the rest of the MIEMSS population, motor vehicle accidents were the predominant cause of injury and multiple injuries were present. Forty-four per cent of the patients had two or more extrathoracic systems involved. The mean age of this group was 42 years, with a range of 16–82 years.

Twelve patients with ruptured aortas died. Three of these patients presented in cardiac arrest. Two patients were in profound shock and had emergent thoracotomies, which disclosed free rupture of the aorta. Of these five deaths, aortic reconstruction was not attempted because of cardiac arrest. There were three late deaths not related to the aortic injury or perioperative course. One death was due to a presumed pulmonary embolus, and one was due to acute respiratory distress syndrome (ARDS) and sepsis. One patient died of an aortic esophageal fistula.[9] Four patients died of factors directly related to their aortic injury and repair. One of the seven survivors had a postoperative paraplegia develop. The total survival rate was 37% and the mortality rate directly related to aortic repair was 21%.

Tracheobronchial Injuries

Rupture of the thoracic tracheobronchial tree is a rare but serious injury in blunt trauma.[10] Kirsh and Sloan[6] have proposed three theories as to the cause of the injury. The first theory states that forceful compression to the thorax pulls each lung apart, with the resulting traction on the trachea and carina producing a tear. A second theory states that high intrabronchial pressure secondary to a closed glottis makes the tracheobronchial tree vulnerable to injury with sudden impact to the chest. A third theory is based on shearing forces on the tracheobronchial tree between the relative stationary areas of the cricoid cartilage and carina with decelerating forces.

Because many persons with disruption of the tracheobronchial tree do not survive, a true incidence of this injury is difficult to determine. In our series, we limited our reporting to the tracheobronchial injuries confined to the thorax and had four such patients. Of these patients, three had tracheal injuries within 2 cm of the carina and one had a mainstem bronchial tear. Three tears were primarily repaired, and one injury consisting of a small carinal tear was treated with expectant observation. Three of the four patients had injury of two or more extrathoracic systems. Two deaths occurred during initial resuscitation (within 6 hours of injury) and were due to multiple injuries. One survivor subsequently had bilateral pleural empyemas develop and the other patient had tension pneumopericardium develop that was treated by open pericardial drainage.

Flail Chest: Pulmonary Contusion

Crushing chest wall injuries resulting in flail chest most commonly occur from motor vehicle accidents; however, they are also associated with compression injuries, falls, and direct blows. The injury causes multiple fractured ribs, creating a segment of chest wall that has lost its continuity with the remainder of the thorax. This produces the paradoxic respirations that are frequently present with flail chest. Flail chest constitutes a serious chest wall injury, and its high morbidity and mortality are mainly due to underlying pulmonary injury and associated injuries.

Pulmonary contusion, defined as injury to lung parenchyma resulting in edema and interstitial hemorrhage, usually is the result of acceleration–deceleration forces. Although often subtle and overlooked when more dramatic injuries are present, its potential to be progressive and develop into respiratory insufficiency underlines its serious nature.[11]

In our series, there were 63 (10.3%) flail chests. The majority of these injuries occurred in patients with multiple injuries. In patients with flail chests, 53.9% had two or more extrathoracic systems injured; only 14.3% of patients had injuries confined to the chest. We report a mortality rate of 28.6%. There were 39 major pulmonary complications within the group, the most common being prolonged intubation (greater than 1 week), pneumonia, and ARDS. Of these 63 patients, 31 (49%) sustained pulmonary contusions and bilateral pulmonary contusion developed in three patients. In the general group, there were 113 unilateral pulmonary contusions and 21 bilateral contusions or 30%.

Cardiac Contusions

Cardiac contusion from blunt chest trauma occurs frequently, ranging from 16% in autopsy studies[12] to 76% in clinical studies.[13] The clinical presentations of such injuries are extremely variable and are frequently unnoticed in the multitraumatized patient. The spectrum of symptoms and signs ranges from the asymptomatic patient to the patient with severe cardiac compromise. Arrhythmias and conduction defects are the most common complications of cardiac contusions.

The heterogeneity of cardiac contusions is related to the evolving method of diagnosis. The most sensitive method for diagnosis is probably an understanding of the mechanism of injury, awareness of possible associated injuries, and a high index of suspicion. Other methods include admitting and serial electrocardiograms (ECGs), assessment of cardiac isoenzymes, two-dimensional echocardiogram, multiple gated acquisition (MUGA) scan, and evaluation of Swan–Ganz thermodilution cardiac output.[14,15] The more compulsively the diagnosis is pursued, the more frequent is the reported incidence.

The usual clinical course is therefore one of resolution. However, in the acute injury phase, morbidity could be high. A small number of patients with high morbidity will develop a course of chronic arrhythmias or overt cardiac compromise. The incidence of morbidity is probably multifactorial, relating to size and location of contusion, premorbid cardiac status, and associated injuries.

In our series, we identified 33 patients with cardiac contusions. The diagnosis was made using ECG in two, MUGA scan in 11, echocardiogram in four, cardiac isoenzymes in two, thermodilution cardiac output in two, and gross inspection of the heart during thoracotomy in four. Eight patients carried the diagnosis of cardiac contusion without a specific diagnostic test listed. There were four deaths in this group: three patients died during the acute resuscitative phase, presenting with shock, and one (late) died of sepsis. In two patients, significant arrhythmia developed that was controlled medically (one with premature ventricular contractions [PVCs] controlled with lidocaine and one with bradycardia controlled with atropine and a temporary pacer). A persistent right bundle branch block developed in one patient. Although no late follow-up information was available, no patient had persistent symptoms of cardiac compromise on discharge.

Cardiac/Pericardial Injuries

Cardiac lacerations from blunt trauma are usually lethal injuries that are frequently diagnosed postmortem. There are scattered case reports in the literature of survival from this injury; however, the insult to the heart and concomitant associated injuries frequently result in death.[16] Pericardial injuries have also been reported as a cause of morbidity and mortality.[17]

In our series, there were 14 cases of cardiac lacerations and no survivors. Eight of the 14 patients arrived with no vital signs, five patients had severe hypotension (initial blood pressure <60 mmHg), and one patient had stable vital signs initially that rapidly changed to significant hemodynamic instability. Emergency thoracotomies were performed in the admitting area on all patients. The injury pattern to the heart involved all chambers, with four injuries involving the right ventricle, three injuries to the right atrium, two injuries to the left atrium, and one injury to the left ventricle. Four patients had injuries involving a combination of two injured chambers. Seven patients had two or more associated injuries. All patients had tamponade before thoracotomy, and a repair or attempt at primary repair using horizontal pledgetted sutures was done in all cases.

An additional four patients sustained pericardial tears that did not violate the cardiac chambers. Two of the four patients arrived with no vital signs; emergency thoracotomies were unsuccessful. One patient arrived in shock and quickly became asystolic; again, emergency thoracotomy was unsuccessful. The fourth patient arrived with stable vital signs and was taken to the operating room for repair of associated intra-abdominal injuries. A thoracotomy was performed because of ongoing hemothorax. Parenchymal injury to the lung was present, associated with a tear in the pericardium, which

was repaired. There was no cardiac injury, and the patient had an unremarkable course.

Great Vessel Injuries

Like injuries to the aorta, an insult to the branches of the aortic arch, thoracic vena cava, or pulmonary hilar vessels connotes a life-threatening injury. A majority of patients with these injuries have severe concomitant injuries and die at the scene or are dead on arrival. A diagnosis of great vessel injury is made by having a high index of suspicion from the mechanism of injury, associated injuries, and physical examination and detection of an abnormal mediastinum by chest x-ray. A suspicion of such an injury mandates an aortic arch arteriogram.

Nine patients presented to the MIEMSS Shock Trauma Center with great vessel injuries other than aortic tears. These included three patients with innominate artery injuries, two patients with subclavian artery avulsions, two patients with axillary artery injury, one patient with injury of the azygous vein, and one patient with an avulsed pulmonary artery and pulmonary vein. There were two deaths and three major complications. One death occurred 48 hours after injury and was secondary to significant preoperative hypotension and low flow state. The second death was late (>4 weeks) and due to sepsis. The complications included empyema, brachial plexus injury, and sternal dehiscence.

Discussion

Blunt thoracic trauma is responsible for one fourth of all traumatic deaths in the United States. In our analysis, we have identified several areas of interest.

The absence of rib fractures or other bony thoracic injuries does not preclude other serious chest injuries. Indeed, 47.4% of the ruptured aortas, 43.5% of the ruptured diaphragms, 50% of the tracheobronchial injuries, and 60.6% of the cardiac contusions presented in the absence of thoracic fractures. Whether this occurs because the energy of acceleration/deceleration forces is not dissipated through the fractures or because a specific type of kinetic force predisposes the patient to soft tissue injury instead of bony injury is unclear. Of importance is that a serious thoracic injury may be present without associated rib or other overt thoracic fractures. To identify these patients, an index of suspicion for blunt thoracic trauma must be maintained based on history, mechanism of injury, and physical examination, despite the absence of fractures.

Within our group of patients with ruptured diaphragms, we identified a high incidence of right-sided diaphragmatic injuries. Although the majority of ruptured diaphragms continued to predominate on the left side, 30% were right sided, a figure much higher than the 5–10% that is often cited. The right-sided lesions are often more subtle in presentation radiographically and can represent a missed injury if an index of suspicion is not raised.[7]

Emergency room thoracotomies continue to be controversial in blunt trauma. All patients in this study who had absent vital signs in the emergency room died despite aggressive resuscitative measures, which included emergency left thoracotomy (39 patients). Emergency thoracotomy might be effective in the treatment of a ruptured cardiac chamber or severe pulmonary parenchymal laceration. However, all patients with these injuries died despite emergency thoracotomy.

The dismal results of our emergency thoracotomies reflect the findings in other studies, which indicate that patients with absent vital signs at the scene, or for greater than 30 minutes after injury, cannot be resuscitated.[18] Nevertheless, because the decision to perform an emergency thoracotomy requires an immediate decision, often with incomplete and inaccurate data concerning the patient, we hesitate from making sweeping recommendations concerning emergency thoracotomies.

Our general philosophy remains that if there is any doubt about a patient's immediate or subsequent clinical status, it is better to err on the side of resuscitation rather than declaring the patient dead on arrival. However, if the patient has no vital signs at the scene or has been without vital signs for 30 minutes, this represents a nonsalvageable patient.

Morbidity

We identified 185 patients (36%) with a morbidity secondary to their chest trauma (Table 3). Atelectasis, confirmed radiographically and significant enough to cause fever and require bronchoscopy or vigorous physical therapy, was the most common complication. Pneumonia, ARDS, and recurrent pneumothoraces were other common complications. An unusual complication of a ruptured thoracic aorta was an aortoesophageal

fistula that presented several months after successful repair and subsequently proved fatal.[9] In general, we believe that early mobilization, aggressive analgesia, vigorous physical and respiratory therapy, and bronchoscopy, if other measures fail, are essential in reducing the majority of pulmonary complications from chest trauma.

Mortality

The mortality rate in this study was 15.5%, representing 80 patients (Table 4). Fifty-nine of these patients arrived with absent vital signs or had cardiac arrest within 1 hour of their arrival. Eight patients died of a primary insult to their central nervous system. There were 16 late thoracic deaths (defined as deaths after 72 hours of hospitalization and primarily related to their thoracic trauma). The causes of death included ARDS, sepsis, heart failure, and multiple organ failure (Table 5).

Malignant Melanoma

Practical Considerations Concerning Prophylactic Regional Lymph Node Dissection

ALLAN W. SILBERMAN, M.D.

Seventy-three patients had 77 prophylactic regional lymph node dissections (PRLND) in addition to wide excision of the primary lesion for clinical Stage I primary malignant melanoma. The preoperative evaluation, surgical procedure, and postoperative follow-up were performed by one surgical oncologist. Seven patients had micrometastatic disease in the regional nodes for a yield of 9.6%. Considering only patients with Clark IV and V melanomas, and Clark III melanomas ≥ 2.00 mm, the yield was 15.6%. The most optimistic, published survival statistics demonstrate a 25% 5-year survival advantage for patients who have PRLND with an incidence of occult nodal disease of 14.3%; thus, even the most optimistic data would predict that only a modest number of patients would actually benefit from surgery. It is difficult to justify PRLND for its therapeutic benefit unless a higher yield of positive-node patients is obtained or the surgical indication is for staging or prognostic information.

From the Department of Surgery, Cedars-Sinai Medical Center, UCLA School of Medicine, Los Angeles, California

IT REMAINS CONTROVERSIAL whether prophylactic regional lymph node dissection (PRLND) should be considered in patients who have primary malignant melanoma and clinically negative regional lymph nodes. The advocates point out correctly that surgery is the only effective therapy for regional lymph node disease; moreover, in several retrospective studies a survival advantage by as much as 25% has been demonstrated in patients with clinically negative but pathologically positive regional lymph nodes.[1,2] Roses et al, from New York University, demonstrated a statistically significant 5-year cumulative survival rate of 57% for 60 patients with clinically negative, but pathologically positive, lymph nodes compared with a 33% 5-year cumulative survival rate for 35 patients with clinically positive and pathologically positive lymph nodes.[1] Balch et al, from the University of Alabama, reported that patients with intermediate-thickness melanomas (1.5–3.99 mm) had a survival rate at 8 years of 78% when treated by wide excision of the primary melanoma and elective lymph node dissection compared with no survivors with wide excision alone.[2]

The opponents of PRLND point to the randomized, prospective, multi-institutional study by Veronesi et al., of the WHO Melanoma Group, which failed to demonstrate any survival advantage in patients who have prophylactic lymph node dissection.[3] In the WHO study, 267 patients were randomized to excision of the melanoma with immediate lymph node dissection and 286 patients to excision of the primary lesion and regional lymph node dissection at the time of appearance of metastases.

The advocates counter with the argument that the WHO study was flawed in that the percentage of women in the study was too high (81%). This is of concern since the incidence of melanoma is approximately equal between the sexes; thus, in a prospective randomized study, one would predict that the number of men and women accrued would have been about the same. In addition, women overall fare better than men with their disease, even when corrected for stage.[4] Thus, a large, lower-risk group was included in an adjuvant (PRLND) study, making it more difficult to demonstrate small, but statistically significant, differences. Also of concern is that the subgroup of patients with Clark IV melanomas having PRLND did, in fact, have a survival advantage (70.1% *vs.* 58.3% 5-year survival rate) as did the subgroup with intermediate-thickness melanomas (1.6–4.5 mm) (78.5% *vs.* 69.7% 5-year survival rate). Since these differences were not statistically significant, it was concluded that these differences were not real. However, an equally valid conclusion would be that the

Submitted for publication: February 5, 1987.

differences were real, but that there were not enough patients in the subgroups (Clark IV subgroup: 178 patients; intermediate-thickness subgroup: 187 patients) to demonstrate statistical validity. Finally, the multi-institutional, international nature of the study (17 institutions, 12 countries) may be considered a flaw since it implies that the preoperative evaluation, the surgical technique, and the postoperative follow-up may have varied considerably.

This report summarizes one surgeon's experience with PRLND for clinical Stage I malignant melanoma. The advantage of this type of analysis is uniformity in pre- and postoperative care and surgical technique.

Methods

All patients referred with clinical stage I malignant melanoma whose histopathologic examination revealed a Clark IV or V lesion or a thick Clark III lesion had PRLND in addition to a wide and deep excision of the primary lesion. With ambiguous lesions, a Tc 99-dextran lymphatic drainage study was performed to delineate the appropriate lymph node group to be resected. The preoperative evaluation, surgical procedure, and postoperative follow-up were performed by one surgical oncologist.

Results

Between September 1980 and June 1986, 73 patients (29 women and 44 men) had 77 PRLNDs for primary malignant melanoma (Table 1). This included 40 axillary dissections, 21 superficial (inguinal) groin dissections, and 16 modified radical neck dissections. There was 100% follow-up. There was no operative mortality. The long-term morbidity consisted of local numbness in all patients regardless of type of lymph node dissection. After superficial groin dissection, some swelling of the lower extremity could be noted in almost all patients if both limbs were carefully measured. In the 21 patients who had superficial groin dissection, four patients have had obvious lymphedema develop, requiring some change in life style. The long-term morbidity after axillary or modified radical neck dissection has been negligible.

The histopathologic findings consisted of 47 Clark III lesions, 26 Clark IV lesions, and one Clark V lesion (Table 2). The Clark level could not be determined in three patients. In the Clark III group, the Breslow thickness ranged from 0.69 mm to 4.9 mm. In the Clark IV group, the Breslow thickness ranged from 0.87 mm to 7.2 mm. The Clark V lesion had a Breslow thickness of 6.5 mm. In two patients, the Breslow depth could not be determined.

In the group of 38 patients who had 40 axillary lymph node dissections, the average number of lymph nodes examined was 25 (median: 24; range: 10–56). There were four positive dissections in four patients. In the group of 21 patients who had 21 superficial groin dissections, there was an average of 18 lymph nodes examined (median: 18; range: 8–30). There were two positive dissections. In the group of 16 patients who had 16 modified radical neck dissections, there was an average of 25 lymph nodes examined (median: 24; range: 10–65). There was one positive dissection. Overall, seven dissections in seven patients were found to contain lymph nodes with micrometastatic disease (Table 3). The per cent yield then was seven positive dissections of 77 dissections (9.1%) or seven positive dissections in 73 patients for a yield of 9.6% (Table 1). In the 66 patients who had negative lymph node dissections, metastatic disease developed in nine patients (13.6%) (Table 4).

Discussion

The controversy surrounding prophylactic regional lymph node dissection in patients with clinical Stage I malignant melanoma continues despite the Veronesi study that failed to demonstrate a therapeutic benefit for patients who have prophylactic node dissection.[3] The reasons for this are several-fold. First, the Veronesi study, as noted above, has several flaws that detract from its conclusions. Second, many patients, after considering the risks and benefits of elective lymph node dissection, believe that the possible small benefit from surgery outweighs the risks. In addition, the patient is often interested in the prognostic information obtained from the lymph node dissection since pathologically negative nodes puts the patient in a lower risk category compared with patients with pathologically positive nodes. Also, adjuvant trials often require the patients to have lymph node dissection for accurate staging before the onset of therapy. Thus, the surgical oncologist, when faced with a new patient with clinical Stage I melanoma, must still make a decision regarding PRLND.

From the therapeutic point of view, the only patients that currently benefit from PRLND are those whose nodes are positive and who are free of distant metastatic disease, *i.e.*, the patient classified as N_1M_0 by the TNM classification. Clearly, not all patients with positive nodes benefit from PRLND since many, if not all, are pathologically N_1M_1 at the time of surgery. Thus, if the incidence of occult metastatic disease in the regional nodes is only 15% in patients with clinical Stage I disease, then the actual number of patients being benefited therapeutically is small. In the study of Roses et al., the incidence of positive nodes in clinically negative patients was 14.3%.[1] Even if we assume that the 25% 5-year survival advantage observed by Roses et al. (comparing patients with clinically negative nodes who had PRLND with patients with clinically positive nodes who had therapeutic node dissection) is correct, it becomes evident that only a very small number of patients actually benefit from PRLND. The mathematics, then, even using the most optimistic survival data, make it difficult to justify PRLND for its therapeutic benefit.

However, PRLND could be justified if the yield of patients with positive nodes were higher. This could be accomplished by selecting patients with thicker lesions for lymph node dissection. In our series, by raising the criteria for surgery to Clark IV and V lesions and Clark

AWD = Alive with disease.

III lesions ≥ 2.00 mm, the yield of patients with positive nodes would have been increased from 9.6 to 15.6%. This is similar to the incidence of positive nodes observed in the study of Roses et al.[1]; thus, the therapeutic advantage obtained could only be modest at best.

However, a higher yield may also be obtained by more accurate pathologic review. Cochran et al. have shown that S-100 protein staining in addition to standard hematoxylin and eosin (H & E) staining may increase the number of positive nodes by as much as 2–3 fold.[5,6] In one study, sections of 1273 nodes from patients with melanoma were stained in an immunoperoxidase assay using an antiserum to S-100 protein and aminoethyl carbazole as an indicator. By the H & E technique, 128 nodes were seen to contain melanoma; by the anti–S-100 technique, 363 nodes were found to be tumor-positive.[5] In a second study, Cochran et al. found that the likelihood of finding occult micrometastatic melanoma in the regional nodes using the S-100 protein staining technique increased with increasing melanoma thickness.[6] In a group of 72 patients who were pathologically determined as Stage I by H & E staining, using anti–S-100 staining, they found micrometastatic disease in 4% of patients with a Breslow thickness of ≤1.5 mm, in 12% of patients with a Breslow thickness of 1.5–3.0 mm, and in 17% of patients with a Breslow thickness ≥ 3 mm. Inaccurate pathologic staining may explain why approximately 15% of patients with negative nodes have recurrence, *i.e.,* they did in fact, have positive nodes unrecognized by standard H & E staining.

PRLND can also be justified as a means to obtain prognostic information and as an entrance requirement for an adjuvant trial, since accurate staging is important in evaluating adjuvant therapy. However, the minimal therapeutic benefit would have to be clearly explained to the patient if the indication for surgery were for prognostic or staging information.

This report is by a surgical oncologist who believes that the removal of microscopic disease, as opposed to gross nodal disease, must be to the patient's benefit. As a result, all patients referred with Clark IV and V malignant melanomas and thick Clark III malignant melanomas had PRLND in addition to wide excision of the primary lesion. However, given a yield of only 15% in patients with clinically negative regional lymph nodes, the mathematics, even with using the most optimistic survival data, make it difficult to justify PRLND for its therapeutic benefit. Pathologic evaluation with anti–S-100 staining may increase this yield sufficiently to justify PRLND in the future.

A Comparison Between 25% Albumin and 6% Hydroxyethyl Starch Solutions on Lung Water Accumulation During and Immediately After Cardiopulmonary Bypass

PHILIP D. LUMB, M.B., B.S.

From the Departments of Anesthesiology and Surgery, Durham Veterans Administration Medical Center, and Duke University Medical Center, Durham, North Carolina

Six per cent hydroxyethyl starch was compared prospectively with 25% albumin as the oncotic component of cardiopulmonary pump prime solutions. Oncotic pressure of the pump prime solution was measured, and serum oncotic pressure (OP) values were recorded at designated times during the perioperative period. Changes in these values were compared with alterations in extravascular lung water (EVLW), the serum oncotic pressure–pulmonary artery occluded pressure gradient and the alveolar–arterial difference in oxygen tension [D(A-a)O_2] before and immediately after bypass and in the surgical intensive care unit after operation. A significant increase in EVLW was associated with a decrease in serum OP and an increase in D(A-a)O_2 immediately after bypass. However, EVLW values had returned to baseline by time of determination in the surgical intensive care unit. Cost savings may be realized by the use of hydroxyethyl starch in this setting if average wholesale price data are representative of costs throughout the country.

POSTOPERATIVE AND POSTRESUSCITATION pulmonary dysfunction have been linked to increases in extravascular lung water (EVLW) and associated changes in the gradient between serum colloid oncotic pressure (COP) and the pulmonary artery occluded pressure (PAOP).[1] Although no differences in pulmonary oxygenation, myocardial behavior, and glomerular filtration rate have been reported after cardiopulmonary bypass (CPB) procedures in which colloid and noncolloid pump primes were compared,[2] a recent study suggests that colloid is preferable to crystalloid in pump prime solutions.[3] Several studies have indicated that 6% hydroxyethyl starch (Hes) (Hespan,® American Critical Care, Division of American Hospital Supply Corporation, McGaw Park, IL) is an acceptable substitute for 5% albumin in pump prime solutions, and after CPB causes no change in chest tube drainage, fluid balance, or blood product use although transient decreases in platelet count were noted.[3–8] Interest in decreasing the cost of medical care has made the question of alternative forms of treatment germane, and the purpose of this study was to determine whether or not the use of Hes as a substitute for 5% albumin in cardiopulmonary pump prime solutions altered EVLW accumulation and pulmonary function in the immediate post bypass period and early postoperative recovery period.

Methods

After obtaining institutional approval and informed patient consent, two groups of 10 patients were prospectively studied. The pump prime was formulated in identical fashion for the two groups (Table 1) with the single difference being the addition of 150 mL of 5% albumin in one group *versus* the addition of 500 mL of 6% Hes in the second group. Patients were randomized to receive either an Hes-containing prime or the standard albumin solution. No changes in preoperative patient preparation or anesthetic management were made. Patients continued receiving cardiac medications up to surgery and all were premedicated with 10 mg of oral diazepam. No attempt to blind the study was made. Consecutive consenting patients for coronary artery bypass grafting (CABG) were used because the study called for a test of fluid shifts during CPB, and patient selection was not believed to play a major role in this process. CABG procedures without valve replacement were selected to standardize surgical manipulation and cross-clamp and total bypass times.

Each patient served as his own control. Change in pulmonary function was measured by the alveolar–arterial difference in oxygen tension (D(A-a)O_2), and it was

compared with changes in EVLW and the COP–PAOP gradient determined before and after CPB and in the surgical intensive care unit (SICU). Additionally, changes in EVLW and serum oncotic pressure (OP) were compared with a control value after anesthetic induction but before CPB, and determinations made immediately on separation from the bypass circuit, before transfer from the operating room to the SICU, during the evening after surgery after stabilization in the SICU and on postoperative day 1. Volume infusion before obtaining the first and subsequent EVLW measurements was minimized and similar in all cases. OP measurements were performed on the pump prime solution. All OP determinations were performed in duplicate on a Wescor Model 4100 colloid osmometer (Warren E. Collier, Inc., Boston, MA), which uses a specially modified Statham P231D transducer (Statham Instruments, Oxnard, CA) with built-in negative offset. Lung water determinations were performed in duplicate using a thermal/dye double indicator technique that has been previously described (American Edwards Model 9310 lung water computer, American Edwards Laboratories, Santa Ana, CA).[9] The technique requires placement of a femoral arterial, thermistor-tipped catheter that is connected to an infusion-withdrawal pump and to the lung water computer. This catheter was placed by the operating surgeon after induction of anesthesia and full patient preparation to avoid chances of contamination in the surgical field. During CPB the lungs were inflated with a continuous low flow of oxygen at 1–2 cm H_2O PEEP and the left ventricle was vented. All patients received continuous infusions of sodium nitroprusside and nitroglycerin after CPB to maintain a mean systemic pressure of 90 mmHg or less. Statistical analysis used analysis of variance with repeated measures. A value of $p < 0.05$ was considered significant.

Statistical Results

Extravascular Lung Water Changes (Tables 2 and 3)

Within each group, significant changes occurred in EVLW (Table 2) and OP (Table 3) between pre-CPB and post-CPB values. However, there were no significant differences between groups. Control values were reached for all parameters by the time of patient entry into the SICU. Although a trend relating increasing EVLW to decreasing OP was noted, it did not achieve significance.

Changes in $D(A\text{-}a)O_2$ Values (Table 4)

No significant differences existed between the albumin and Hes groups. A highly significant difference ($p < 0.0005$) was noted between control and $D(A\text{-}a)O_2$ on postoperative day 1 in both groups, and this was associated with an increase in OP–PAOP gradient and a decrease in EVLW to control value at this time. In the Hes group a significant difference was seen between control and post-CPB OP–PAOP gradient; however, no difference was noted in the albumin group or between groups for this parameter.

Discussion

Although accumulation of lung water after CPB has been reported, some authors have failed to demonstrate any increase.[4] Previous discussions have speculated on various causes of lung water accumulation after CPB, and most include discussions of the balance between the microvascular hydrostatic pressure and the plasma colloid oncotic pressure.[4,10] Additionally, the use of Hes as an effective volume expander in CPB[3,6,7] and in hypovolemic and hemorrhagic shock[11-15] is well demonstrated. Although other factors have been implicated in accumulation of lung water after CPB (pulmonary capillary leak,[16] complement mediated leukostasis,[17] and changes in the pulmonary circulation secondary to high generated pressures or atelectasis during bypass[4]), no study has documented the immediate changes in lung water seen at the termination of CPB and compared with a pre-pump control value. No patient had severe postoperative cardiac dysfunction develop. However, the experimental design was such that changes in EVLW as a result of CPB could be isolated from later cardiac dysfunction and the known changes in COP occurring because of interstitial fluid shifts and the release of preformed albumin into the circulation.[18]

From the results in Tables 1–4, the following conclusions are drawn: (1) The oncotic pressure is similar with Hes and albumin primes. (2) CPB decreases COP and increases EVLW. (3) Early postoperative increases in

† $p < 0.005$ compared with pre-CPB values.

$D(A\text{-}a)O_2$ are associated with an increase in EVLW and decrease in the COP–PAOP gradient. These changes reversed over time and had returned to control values by completion of the study on postoperative day 1. (4) No significant difference can be shown between Hes or albumin as a pump prime colloid solution. (5) Additionally, it is likely that significant cost savings may be realized by adopting Hes as a routine pump prime solution instead of albumin.

Unlike Byrick et al.,[10] we noted the maximal increase in EVLW to be associated with termination of CPB, therefore suggesting that bypass itself is causative. Additionally, in agreement with Gallagher et al.[4] and in contrast with Byrick et al.,[10] lung water decreased from the values obtained after CPB and returned to control values on postoperative day 1. This, indeed, may reflect a greater COP in the postoperative period, and it is likely that in the postoperative period, hydrostatic-oncotic pressure differences may be primarily responsible for regulating fluid flux across the lungs.

Additionally, the results in this study differ slightly from those of Gallagher et al.[4] in that a significant increase in EVLW was noted after CPB. However, this increase was transient and ceased to be statistically significant by the time determinations were performed in the postoperative SICU. Therefore, when time courses are similarly compared, the results of these two experiments are in accord, and both differ from the reported levels of Byrick et al.[10]

Cost savings per pump prime are approximately $170.00 by substituting one 500-mL bottle of Hes for 150 mL of 5% albumin solution.

Conclusions

This study confirms previous reports that postoperative accumulation of lung water is not significant if measured in the postoperative intensive care unit. However, transient but statistically significant increases were shown immediately after CPB. $D(A\text{-}a)O_2$ values increased in both groups after CPB, but this was not significant statistically nor clinically, although pre-CPB values were high and may represent 100% inspired oxygen-induced atelectasis and intrapulmonary shunt. No difference was shown between the choice of 25% albumin or 6% Hes solutions in the pump prime with respect to oncotic pressure of the prime itself or to the changes in EVLW measured during CPB. Mild changes in pulmonary function as reflected by an increase in $D(A\text{-}a)O_2$ were associated with a decrease in COP and increase in the COP–hydrostatic pressure gradient, suggesting that these are the major determinants of lung water change. Substantial financial savings may be realized by the substitution of albumin with Hes in cardiac pump prime solutions without altering operative outcome.

Regulation of Lipolysis in Severely Burned Children

ROBERT R. WOLFE, DAVID N. HERNDON, EDWARD J. PETERS, FAROOK JAHOOR,
MANU H. DESAI, and O. BRYAN HOLLAND

In this study, the rates of lipid mobilization and of lipolysis have been quantified in severely burned children. In all 12 patients studied, the basal rates were determined. In seven patients, the lipolytic responsiveness to an infusion of epinephrine (0.015 μg/kg/min) was tested, and in the other five patients, the response to beta-adrenergic blockade (propranolol, 1 mg/kg) was tested. The rate of appearance (Ra) of free fatty acids (FFA) was quantified by means of the infusion of 1-^{13}C-palmitate to determine the rate of lipid mobilization, and Ra glycerol was determined using d_5-glycerol to assess the rate of lipolysis more directly. In five patients, body composition was determined after recovery by means of $H_2{}^{18}O$ dilution. The basal rate of lipolysis was higher than normal in the burned children. In four of the seven patients infused with epinephrine, there was a pronounced increase in Ra glycerol. In all patients given beta-blockade, Ra glycerol decreased greatly. Changes in Ra FFA corresponded with the changes in Ra glycerol in each case. Total body fat was very low (approximately 2% body weight), reflecting the surgical removal of fat in the process of burn wound excision. From these data it is concluded that lipolytic responsiveness to catecholamines in severely burned children is variable, but not absent, despite chronically elevated levels of catecholamines. The total extent of lipolysis may be limited by the available fat mass in children treated with fascial excision. In such patients, the limitation in the ability to mobilize an adequate amount of FFA to fully meet energy requirements provides an important rationale for the clinical practice of providing nutritional support in hourly boluses, as opposed to infrequent meals, since any period of even a few hours in which nutrients are not being absorbed will result in an energy substrate deficiency and consequent increase in amino acid oxidation.

Biochemistry, Internal Medicine, and Preventive Medicine,
The University of Texas Medical Branch, and
Shriners Burns Institute, Galveston, Texas*

THE ABILITY TO MOBILIZE endogenous fat is essential for energy balance because free fatty acids (FFA) normally serve as the major energy source in the postabsorptive state. Fatty acid kinetics are, therefore, important in any pathologic state. The ability to mobilize endogenous FFA in severe burn injury is particularly important because of the increased rate of energy expenditure.[1]

Previous studies in animals[2] and human patients[3,4] have shown that basal FFA flux is elevated after burn or other forms of traumatic injury. Since catecholamines are potent stimulators of lipolysis,[5] and since catecholamines are chronically elevated in severely burned patients,[6] one would expect that the catecholamines play an important role in the stimulation of lipolysis in burned patients. However, the only previous study in which FFA kinetics were determined in burned patients raised doubt as to the importance of the catecholamines in stimulating lipolysis, since these authors failed to identify any relationship between FFA flux and the plasma catecholamine concentrations.[3] However, there are reasons to further explore the role of the catecholamines in stimulating lipolysis in burned patients. First, FFA flux is a reflection not only of lipolysis, but also of the rate of re-esterification of fatty acids within the adipocyte before entering the plasma. The rate of release of glycerol is a better reflection of lipolysis than FFA flux. Glycerol appears in the plasma only as a result of lipolysis,[7] and glycerol cannot be re-esterified within the adipocyte.[8] Thus, all free glycerol resulting from lipolysis appears in plasma. Secondly, a quantitative relationship between plasma catecholamine concentration and lipolysis might not be expected throughout the en-

tire range of plasma catecholamine concentration encountered in burn patients. In some patients, catecholamine concentrations are so high that they probably greatly exceed the value of maximal biologic effectiveness. Also, the sensitivity to catecholamines may be altered, such that a level of plasma epinephrine that is below the threshold for lipolytic stimulation in normal individuals[9] may be effective in stimulating lipolysis in burned patients.

In this study, we have used two approaches to assess the effectiveness of catecholamines in stimulating lipolysis after severe burn injury: (1) we determined the lipolytic responsiveness to an infusion of epinephrine, and (2) we determined the response of lipolysis to beta-adrenergic blockade. Glycerol flux, as determined with the stable isotopic tracer d_5-glycerol (Cambridge Isotope Laboratory, Woburn, MA), has been used as the indicator of the rate of lipolysis. The rate of flux of palmitate, as a representative FFA, was determined simultaneously with 1-^{13}C-palmitate (Tracer Technology, Newton, MA).

Methods

Patients

The subjects were 12 severely burned children admitted to the Shriners Burns Institute in Galveston. In each case, the purpose of the study and the associated risks were explained in detail to the parents and a patient advocate as part of obtaining informed consent. The study was approved by the Institutional Review Board of The University of Texas Medical Branch in Galveston.

All patients were admitted to the hospital shortly after injury, and after fluid resuscitation were treated with aggressive excisional therapy. Their clinical characteristics are summarized in Table 1. The type of surgical excision used (fascial or tangential) was determined by the judgment of the surgeon. Fascial excision involves removal of the burn wound and everything beneath it (fat) to the level of fascia. Tangential excision, on the other hand, leaves the fat fairly much intact. Each child was maintained in a temperature-controlled room that was adjusted to help maintain the expected body temperature. There was no change in room temperature throughout the study protocol. All studies were performed at least 2 days after the most recent visit to the operating room. The patients were given an average of 108 ± 14.7 kcal/kg/day, with approximately 50% as carbohydrate. Protein intake averaged 3.8 ± 0.56 g/kg/day. This mixture was administered hourly by tube feeding. The tube feedings were terminated 9 hours before the collection of the first samples used for analysis.

All children had a venous and arterial catheter present for clinical purposes. For the purposes of the study, the venous catheter was used for isotope infusion, and the arterial catheter was used for blood withdrawal. After a baseline blood sample, a constant infusion of 1-^{13}C-palmitate and d_5-glycerol was started and maintained for 120 minutes. The palmitate was bound to albumin[10] (Cutter Albumin, Emeryville, CA), and the glycerol was added directly to the albumin–palmitate mixture. The isotopes were infused by means of a calibrated Harvard Syringe Pump (Harvard Apparatus Co., Inc., Natick, MA). The palmitate was infused at approximately 0.04 μmol/kg/min and the glycerol was infused at approximately 0.11 μmol/kg/min, with a prime of 1.6 μmol/kg. The exact infusion rates were determined for each patient by measurement of the concentration of the infusion mixture. The patients were kept supine and as undisturbed as possible throughout the entire isotope infusion.

Samples were taken at 5-minute intervals starting after 30 minutes of isotope infusion. The five samples taken between 30 and 55 minutes were used to determine basal kinetics and concentrations. In seven patients, a constant infusion of epinephrine was started at 55 minutes, at the rate of 0.015 μg/kg/min, through the venous catheter. The epinephrine was constituted in a solution containing ascorbic acid (50 mg) to prevent oxidation. Samples were drawn at 10-minute intervals throughout the 60 minutes of epinephrine infusion.

In five recovered patients, total body water was determined using $H_2{}^{18}O$ for the purpose of calculating the total body fat. A urine sample was obtained, then $H_2{}^{18}O$ (10.45 APE) (Prochem, Summit, NJ) was given orally. The $H_2{}^{18}O$ was administered at a dose estimated to produce an increase of approximately 50 parts per thousand $H_2{}^{18}O$ concentration. All urine produced between 0 and 4 hours after isotope administration was discarded. The first collection after 4 hours was used for the determination of isotopic enrichment, compared with the value obtained before the isotope administration.

In the other five patients, the basal period (isotopes only) lasted 90 minutes; without interruption of the isotope infusion, an infusion of propranolol (Inderal®) then was started. A total of 1 mg/kg, comparable to the dose previously used by Wilmore et al. in burned patients,[6] was given over approximately 10 minutes. Heart rate never decreased below 100 beats/min during the propranolol infusion. Samples were taken at intervals over the next 90 minutes.

Analysis of Samples

The samples for catecholamine analysis were collected in iced tubes containing ethyleneglycol-bis-(beta-aminoethyl ether) N, N^1-tetra-acetic acid (EGTA, 1 mg/mL blood) and reduced glutathione (2 mg/mL blood) and were centrifuged immediately at 4 C. The plasma was separated and stored at −70 C until analysis. Plasma norepinephrine and epinephrine concentrations were determined by a radioenzymatic assay using catechol-o-methyl transferase to label catecholamine-containing compounds with tritium labeled S-adenosyl methionine.[11] Plasma levels of insulin and cortisol were determined by radioimmunoassay using kits from Micromedic (Cambridge, MA). Plasma for glucagon analysis was placed in tubes containing EDTA and Trasylol, for later radioimmunoassay.[12] Plasma glucose concentration was measured on an auto-analyzer (Beckman Instruments Co., Fullerton, CA).

Blood for analysis of palmitate and glycerol enrichment was collected in heparinized tubes and placed immediately in a 4 C ice bath, which prevents the *in vitro* hydrolysis of endogenous triglycerides by lipoprotein lipase.[13] The plasma was promptly separated by centrifugation and frozen until the time of analysis. The samples were processed for quantitative gas chromatography as described by McDonald-Gibson and Young.[14] Heptadecanoic acid (0.05 mg/mL plasma) was added as an internal standard for subsequent measurement of FFA concentration. After conversion to the methyl ester, 1-^{13}C-palmitic acid enrichment was determined by gas chromatography mass spectrometry (GCMS) as described previously[10] using a Hewlett-Packard 5985 GCMS system (Hewlett-Packard, Palo Alto, CA). Ions at mass-to-charge ratios (m/e) of 270.2 and 271.2, representing the molecular ions of unlabeled and 1-^{13}C-palmitic acid methyl esters, respectively, were selectively monitored at 0.1-second intervals and their corresponding peaks integrated. Palmitic acid and total FFA concentrations were quantitated separately on a Hewlett-Packard gas chromatograph.

The blood for glycerol determination was collected in the same manner as that for palmitate. 2-^{13}C-glycerol was added as an internal standard to each sample, except for the background sample. Plasma proteins were then precipitated with $Ba(OH)_2$ and $ZnSO_4$ and the resultant supernatant was passed through anion (Dowex AGI-X8) and cation (Dowex AG-50W-X8) exchange columns. The trimethylsilyl derivative was formed and isotopic enrichment determined by GCMS using electron-impact ionization.[15] Ions were selectively monitored at m/e 205, 206, and 208 to quantify the isotopic enrichment in the plasma resulting from the d_5-glycerol infusion (m/e 208), and to quantify the enrichment that resulted from adding 2-^{13}C-glycerol *in vitro* for the purpose of determining concentration.

^{18}O enrichment was analyzed on CO_2 gas equilibrated with the water in a nonsiliconized, evacuated vacutainer, using a triple-inlet, triple-collector, 6-inch isotope ratio mass spectrometer (Nuclide Corp., State College, PA). Ions at m/e 44, 45, and 46 were each directly collected and monitored.

Calculations

The rates of appearance of palmitate (Ra palmitate) and glycerol (Ra glycerol) were calculated using the Steele equation.[16] In the basal period, when only isotope was infused, a physiologic and isotopic steady state existed, meaning that neither concentration nor enrichment was changing over time. Therefore, the steady-state form of the Steele equation was used.[15] Since palmitate is believed to be typical of other long-chain fatty acids,[17,18] the relationship between flux and concentration of the other fatty acids in plasma was assumed to be the same as for palmitate. Therefore, total FFA flux was calculated by dividing the rate of appearance of palmitate (Ra palmitate) by the fraction of [palmitate]/[total FFA], as determined by gas chromatography.

After the administration of epinephrine or propranolol, the steady state was disturbed. In this case, the non-steady-state form of the Steele equation was used.[16] For palmitate, V (the "effective" volume of distribution) was assumed to be 40 mL/kg, and for glycerol, V was assumed to be 200 mL/kg.

In the rapidly changing non-steady state, the Steele equation often yields unreliable values when raw data are used, because implausible gradients occur in the enrichment/time curve due to random error. Therefore, curve fitting is often necessary to smooth the data. In this experiment, enrichment and concentration data were smoothed by the method of spline fitting, which involves the use of smoothly joined polynomial function segments as a description of experimental data.[19] It is well suited for the data generated in this experiment because the curve-fit data represent the actual data well on small intervals, the values of the fitted curve are little affected by data points that are horizontally distant, and it provides a good overall (least-square) fit.

Once the spline fitting was accomplished, curve-fit data points were taken every 5 minutes throughout the epinephrine or propranolol infusion for the purpose of calculating the Ra. To quantify the magnitude of the response to epinephrine infusion, the area under the Ra *versus* time curve between T = 55 and T = 120 minutes was then calculated according to the trapezoid rule, and the basal value (before epinephrine infusion) was subtracted from the total area.

The estimation of body fat was determined from the calculation of total body water (TBW) as follows[20]:

$$\text{BW (kg)} = \frac{D}{MW} \times \frac{APE}{100} \times 18.02 \times \frac{f}{R_{std} \times \Delta\delta^{18}O}$$

where D is the dose of $H_2{}^{18}O$ (g), MW is the molecular weight of the $H_2{}^{18}O$, APE is the atom percent ^{18}O enrichment of the $H_2{}^{18}O$, f is the ^{18}O fractionation between CO_2 and H_2O (1.0407), $^{R}{}_{std}$ is the ratio of $^{18}O/^{16}O$ in the standard (0.002004) and $\Delta\delta^{18}O$ is the difference between the ^{18}O enrichment in the sample before and 4 hours after isotope administration, compared with our lab CO_2 standard.

and lean body mass (kg) = TBW/0.72

and body fat (kg) = body weight − lean body mass

Statistical Analysis

The experimental design enabled the use of each patient as their own control, in that the value after epinephrine or propranolol infusion was compared statistically with the value in the same patient before the infusion. The resolution of the central questions addressed in this study, *i.e.*, what are the responses to epinephrine or propranolol infusion in burned children? did not require "control" data from unburned children. In some cases, however, we present normal values (determined in our laboratory by the same methods in normal volunteers) as a frame of reference. However, since these normal values were all obtained in adults, they do not serve as adequate "control" values for burned children. Analysis of the responses after infusion with the basal value was performed with either the Student's t-test for paired samples or analysis of variance and Dunnett's t-test.

Results

Epinephrine Infusion (N = 7)

The basal epinephrine concentrations varied widely (range: 72–653 pg/mL), yet the epinephrine infusion caused a relatively consistent incremental increase in epinephrine concentration (Table 2). The average increase was 270 ± 46 (SEM) pg/mL, with a range from 156 to 453 pg/mL. This incremental increase in epinephrine did not result in significant changes in plasma norepinephrine, insulin, or glucagon, all of which were higher than would have been anticipated for normal children.

TABLE 2. *Effect of Epinephrine Infusion on Hormone Concentrations**

Hormone	Basal	Epinephrine Infusion
Epinephrine (pg/mL)	298 ± 87	583 ± 120
Norepinephrine (pg/mL)	1274 ± 420	1171 ± 501
Insulin (μU/mL)	17.2 ± 2.2	14.2 ± 1.3
Glucagon (pg/mL)	310 ± 50	299 ± 49
Cortisol (μg/dL)	37.4 ± 4.5	—

* N = 7, values mean ± SEM.

The rate of epinephrine infusion used (0.015 μg/kg/min) was insufficient to cause significant changes in resting energy expenditure, nitrogen excretion, substrate oxidation (determined by indirect calorimetry), or plasma glucose concentration. Nonetheless, in four of seven patients, the epinephrine infusion caused a pronounced stimulation of lipolysis, as reflected by the rate of appearance of glycerol (Ra glycerol) (Fig. 1). The other three patients, however, did not have any significant lipolytic response to the epinephrine infusion (Fig. 1). The total lipolytic response of each patient for the 60 minutes of epinephrine infusion is shown in Figure 2, as compared with the normal response for adults. Although the response in controls may differ quantitatively in children and adults, the normal value is presented to amplify the dichotomy of response of the burned children. Three of the children apparently had

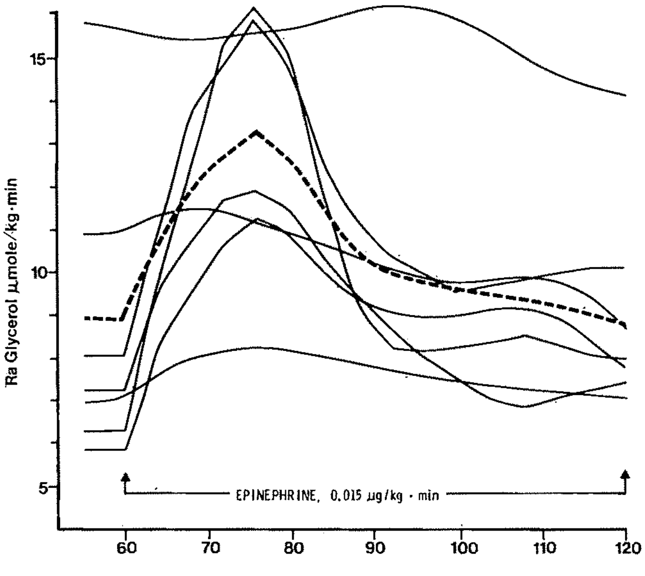

FIG. 1. Rate of appearance of glycerol (Ra glycerol) in seven severely burned children during the infusion of epinephrine. The dotted line represents the mean value and the solid lines represent the individual responses.

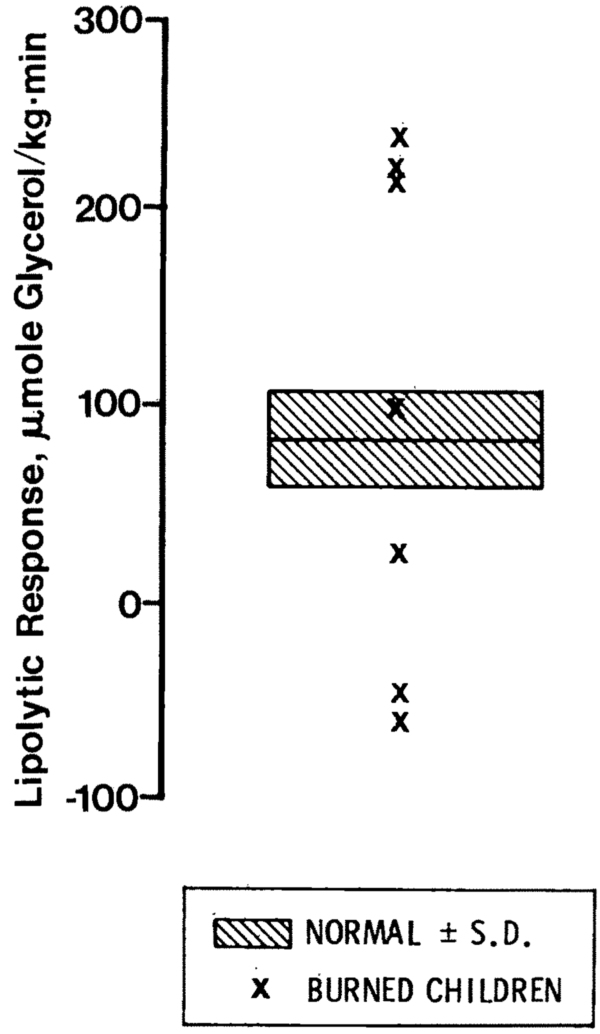

FIG. 2. Total lipolytic response (Ra glycerol *vs.* time) over the 60 minutes of epinephrine infusion. The basal value was subtracted from the epinephrine infusion value. The shaded area represents the mean response, ±SD, of normal adult volunteers (from reference 22).

increased sensitivity to epinephrine, and three were well below the normal level of responsiveness.

Data were evaluated to ascertain a possible explanation for the fact that only some of the patients responded to the epinephrine infusion, despite the consistent elevation in the basal rate of lipolysis in all patients. No consistent difference was found between "responders" and "nonresponders" in the concentration of catecholamines, the basal rate of lipolysis, the percentage of burn, the day after burn, or any other clinical factor measured. The only identifiable variable that may separate the two groups was the extent of fascial, as opposed to tangential, excision in the nonresponders. Those with greater fascial excisions (greater percentage of body surface) had no lipolytic response (Table 3). The estimates of body composition derived from the total body water measurements substantiated that the nonresponders had only a small amount of body fat, as all three such patients had less than 2.5% body fat (compared with the normal value of 15% in age-matched controls, using the same methodology[21]). Although the calculation of exact mass of body fat may be inaccurate with such small amounts of fat, the value of the burned children was clearly far below normal.

The rate of appearance of FFA and plasma FFA concentrations followed the Ra glycerol and glycerol concentrations. The basal values of Ra FFA and FFA concentrations were 14.1 ± 2.1 μmol/kg/min and 0.48 μmol/mL, respectively. The responders reached a peak value of Ra FFA between 22 and 34 μmol/kg/min, and those that did not have an increase in Ra glycerol also did not have an increase in Ra FFA.

TABLE 3. *Effect of Fascial Excision on Lipolytic Responsiveness*

	Lipolytic Response (μmol glycerol/kg h)	% TBSA Fascially Excised
Responders, N = 3	219 ± 14	9 ± 9

Normal values*	86 ± 24	—

* Normal values from reference 22.

TABLE 4. *Effect of Beta-blockade on Hormone Concentrations**

Hormone	Basal	Blockade
Epinephrine (pg/mL)	455 ± 120	—
Norepinephrine (pg/mL)	1843 ± 380	—
Insulin (μU/mL)	22 ± 5	16 ± 3
Glucagon (pg/mL)	330 ± 48	403 ± 52
Cortisol (μg/dL)	26.5 ± 4.5	28.1 ± 5.1

* N = 5, Values are mean ± SEM.

Beta-blockade

The basal hormone concentrations of the patients included in this protocol (Table 4) were comparable to those infused with epinephrine (Table 2), as was their general clinical condition. Infusion of propranolol had no obvious clinical effect, heart rate decreased approximately 15 beats/min, but remained above 100 beats/min in all cases, and no significant change in blood pressure was observed. Subjectively, the patients appeared calmer after the propranolol infusion.

Beta-blockade caused a significant fall in the plasma insulin concentration, but no change in either glucagon or cortisol concentration (Table 4). Nitrogen excretion was not significantly altered by beta-blockade. Although resting energy expenditure fell modestly, this decrease also was not statistically significant (Table 5). Plasma glucose decreased slightly (from 101 ± 9 mg/dL to 93 ± 10 mg/dL) but this also was not statistically significant.

There was a wide range in the basal rate of lipolysis (Ra glycerol ranged from 5.2 to 14.2 μmol/kg/min). Nonetheless, beta-blockade caused a prompt reduction in Ra glycerol in all cases, and this value remained depressed throughout the next 90 minutes (Fig. 3). The plasma concentration of glycerol fell correspondingly. Ra FFA also fell promptly after beta-blockade, from a mean basal value of 13.3 ± 3.1 μmol/kg/min to a low of 7.44 ± 2.33 μmol/kg/min at 40 minutes after propranolol. In all cases after beta-blockade, the potential energy available in the form of plasma FFA was reduced much more than was the overall rate of energy expenditure. All values for Ra glycerol and Ra palmitate after propranolol were statistically significantly lower than the basal values.

Discussion

In this experiment we tested the lipolytic response in burned children to the infusion of epinephrine at a rate sufficient to consistently stimulate lipolysis in normal volunteers.[22] Since lipolysis was stimulated in only four of the seven patients tested, we might conclude that some burn patients become desensitized to the lipolytic action of catecholamines. Such a desensitization response might be expected, since the chronic elevation of epinephrine normally causes a down-regulation of receptors,[5,23] and all of our patients had high levels of epinephrine (presumably for several days).[6] Furthermore, the importance of epinephrine as a lipolytic stimulant in burned patients was questioned by Galster et al.,[3] who failed to find a relationship between the plasma epinephrine concentration and the rate of palmitate flux in burned patients. Alternatively, it is possible that all patients retain responsiveness to the catecholamines, but in some patients the maximum rate of lipolysis was achieved at rest without added infusion of epinephrine.

The principal support for the conclusion that all patients retain responsiveness to catecholamines is the consistent and pronounced decrease in lipolysis observed when adrenergic blockade was given. The decrease in lipolysis was especially impressive, since we probably did not achieve complete blockade despite the large dose of propranolol used (1 mg/kg). In all cases, heart rate remained above 100 beats/min, evidence that some adrenergic stimulation was persisting. Furthermore, blockade caused insulin concentration to fall (Table 4), and a decrease in insulin concentration, by itself, would lead to an increase (rather than decrease) in lipolysis.[7] Thus, the basal adrenergic activity plays an important role in stimulating lipolysis in burn patients.

TABLE 5. *Effect of Beta-blockade on Energy Expenditure**

	$\dot{V}O_2$	$\dot{V}CO_2$	Resting Energy Expenditure	
	(μmol/kg/min)		cal/kg/min	% Predicted
Basal	400 ± 38	318 ± 34	42 ± 4.0	145 ± 26.5
Beta-blockade	340 ± 67	269 ± 58	36 ± 3.3	124 ± 34.1

* N = 5, Values are mean ± SEM.

The fact that epinephrine retains its effectiveness as a stimulator of lipolysis in burn patients, despite the chronic elevation in epinephrine levels, is consistent with the findings of a previous study done in rats. Aprille et al.[24] found that adenylate cyclase from adipose tissue of burned rats retained responsiveness to isoproterenol when assessed *in vitro*. In contrast, adenylate cyclase did become desensitized after isoproterenol injection in unburned rats.[24] The authors proposed that chronic elevations of catecholamines evoke regulatory mechanisms in target cells to circumvent the desensitization that would otherwise occur as a result of acute exposures to catecholamines. It seems this same mechanism is operative in human burn patients as well.

The conclusion that burn patients retain lipolytic sensitivity to catecholamines, however, does not explain the failure of some patients to respond to epinephrine infusion. Although the basal Ra glycerol of the burned pa-

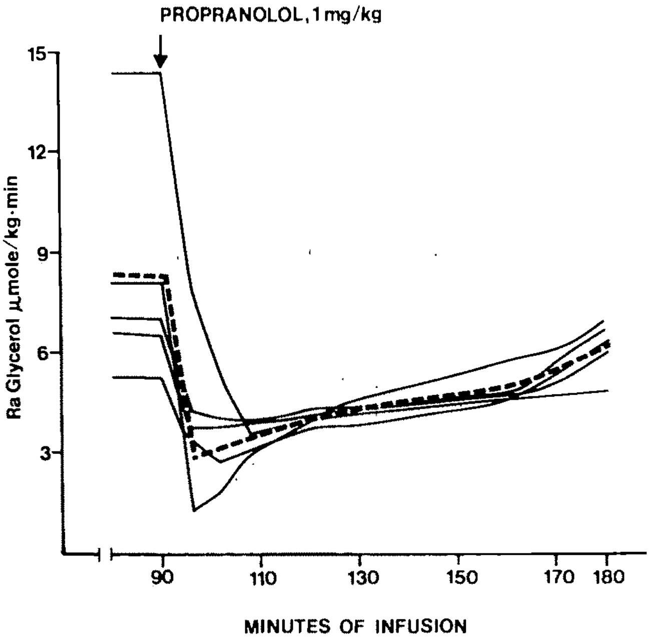

FIG. 3. Response of individual burned patients (solid lines) and mean response (dotted line) to the infusion of propranolol.

tients was higher than normal (mean basal value of 8.9 ± 1.6 μmol/kg/min *vs.* 2.2 ± 0.1 μmol/kg/min for normal adult volunteers, N = 8), the value was on average below the peak attained in normal volunteers fasted for 3 days and then infused with epinephrine at 0.015 μg/kg/min (16.0 ± 2.2 μmol/kg/min).[22] However, one nonresponding patient had a basal value of 17 μmol/kg/min (Fig. 1), and the other basal values of the nonresponders were also high when their limited amount of fat is considered. Although our body composition analysis was performed after recovery, and was thus not necessarily representative of the situation at the time of study, the extremely low percentage of body fat found at that time suggests the body fat mass was limiting in the extent to which lipolysis could be stimulated. This possibility is further supported by the fact that, at the time of study, the nonresponders had a greater amount of fat removed surgically than had those who responded to the epinephrine infusion (Table 3).

Despite the high basal rate of lipolysis in the burned children, the amount of FFA mobilized in the basal state was inadequate to meet energy requirements. The mean basal value of Ra FFA of all patients was 14.2 ± 1.2 μmol/kg/min. If all of this was completely oxidized, it would provide approximately 33 cal/kg/min of energy, assuming 17 carbons per fatty acid and 6.06 cal/mL of CO_2 produced (at an respiratory quotient of 0.70), whereas the overall mean value of basal energy expenditure was 36.4 ± 3.0 cal/kg/min. The inadequacy of Ra FFA to meet energy expenditure fully is further underscored by the fact that normally only 30–40% of Ra FFA is directly oxidized.[25] Since endogenously mobilized fat is the primary source of energy in the postabsorptive state, these severely burned children were in a negative energy balance of carbohydrate and/or protein at all times other than when they were receiving nutritional intake. Thus, it is of clinical interest that administration of beta-blockade had a paradoxical effect. Although it lowered the resting energy expenditure by approximately 6 cal/kg/min (Table 5), the reduction in potential energy available as a result of the fall in Ra FFA during beta-blockade was more than double the reduction in metabolic rate. Thus, beta-blockade would not be expected to have a beneficial effect on nitrogen metabolism in the postabsorptive state after burn injury, even though overall metabolic rate may be decreased. This prediction is consistent with evidence from an animal experiment.[26]

The failure of Ra FFA to increase in proportion to the increased rate of lipolysis in the burned patients is reflected by the low ratio of Ra FFA/Ra glycerol (1.6), compared with the normal value of approximately 3.[22] This is explained by an increased rate of re-esterification of fatty acids within the adipose tissue. Several factors favor a high rate of re-esterification in burn patients. Low serum albumin concentration is one factor. FFA are not soluble in water, and therefore must be transported in plasma bound to albumin. The normal molar ratio of FFA/albumin varies from 0.5 to 1.5.[27] In some patients, the albumin concentration was as low as 2.0 g/dL, or 0.29 μmol/mL, meaning that the FFA/albumin ratio was at the upper range, even though the concentration of FFA was below 0.5 μmol/mL. Not only was the albumin carrying capacity reduced in burned patients, but also the albumin availability most likely was reduced due to a sympathetic nervous system-induced vasoconstriction of blood flow in the fat. This would have no impact on Ra glycerol, since glycerol is dissolved in the water of plasma and the adipose tissue blood flow would not therefore be rate limiting. In contrast, decreased fat blood flow would limit Ra FFA and thus stimulate re-esterification. Also, plasma insulin concentration (and to a lesser extent, glucose concentration), were higher than normal in the patients. High insulin and/or glucose concentration favors re-esterification *in vivo* by increasing the availability of alpha-glycerol-phosphate.[7]

The high rate of re-esterification, coupled with the high rate of lipolysis, means that there was a high rate of triglyceride/fatty acid substrate cycling in burned patients. This high rate of substrate cycling may have contributed to the overall metabolic rate and could explain the apparent enhanced responsiveness to epinephrine infusion in the "responding" burn patients (Fig. 2). One important theoretical advantage of substrate cycling is amplification of control of substrate flux, provided that the Kmax of the enzymes are not approached.[28]

The clinical implication of these studies is that Ra FFA may be limited by the reduced amount of endogenous fat in severely burned children treated with excisional therapy, and this deficiency may have a negative impact on energy metabolism. Although fascial excision reduces the available fat mass and thus magnifies the problem of mobilization of adequate amounts of endogenous energy substrates, the findings of this study do not bear directly on the advisability of this surgical procedure for acute burn care, since with appropriate nutritional support it is possible to counteract any energy imbalance. The long-term effect of the removal of fat, on the other hand, may have important consequences in terms of rehabilitation, particularly with regard to the ability to perform exercise. With regard to the administration of adrenergic blocking agents to lower the metabolic rate, the findings of this study do not provide a metabolic basis for the procedure, since basal adrenergic activity plays a major role in stimulating lipolysis due to intact, or enhanced, lipolytic sensitivity to catecholamines.

Acknowledgments

The authors acknowledge the important contribution of Marta Wolfe for the mass spectrometry analyses. The technical assistance of Susan Fons, Esther Surriga, Glenn Chin, Nitina Seghal, and Boyd Carr was also greatly appreciated. The authors thank Thomas Rutan, R.N., for performing the indirect calorimetry, the nursing staff of the Shriners Burns Institute for help in performing the studies, and Judy Chadwick for typing the manuscript.

Second Thoughts of a Surgical Curmudgeon. Mark M. Ravitch. 240 pp. Chicago: Year Book Medical Publishers. 1987. $12.95.

THE MOMENT THE prospective reader picks up this book and looks at the title, he becomes involved. Curmudgeon. While making mental note of its spelling, his analysis of the word as a title takes him to his dictionary. A school or pocket dictionary will only increase the mystery.

This is a remarkable and valuable book, full of wisdom, information, and stimulating new perspectives on many subjects close to the heart of students and graduates of medicine. It is written in the concise interesting style of this master writer and historian with some gentle humor and whimsy.

The book is a collection of 74 editorials, articles, and lectures by Ravitch, written between 1965 and 1984. The majority are brief and concise. Included is the full text of two superb lectures to the Alpha Omega Alpha. In one of these, for the first two thirds of his address, he apologizes to the audience for the inadequacies of their past education which, by design I am sure, would leave them totally "on side." Whereupon he quietly proceeds to deliver his message: "The focus must always be on the patient. Never lose sight of that." There is a fascinating piece of fiction with drama and suspense, published in *Esquire,* and a delightful spoof on "informed consent."

In selecting the contents, Mark Ravitch avoids science. The early sections deal principally with such subjects as Quality, Language, and Philosophy of a surgeon. Some were written in the late 1960s, of interest to historians and seniors. They are "not rewritten" and it is a sad commentary that many of the problems are still with us.

The later sections are more topical: Education, Medicosocial, and Ethics. Most were written in the 1980s. He is well informed and thought provoking. The patient in the hospital is a concern but he does not explore the concept or use the modern term "quality of life."

Dr. Ravitch's remarkable intellectual curiosity and perception comes through frequently. He tips his hand and tells the reader how he keeps abreast on such a wide front. There is practical advice on presenting and discussing papers and on the use of words. You should keep a dictionary nearby.

Dr. Ravitch's uniqueness is his breadth of interest and awareness of the past. The book is more than "second thoughts." It is an intimate portrait with special insight into the mind and character of a great American surgeon. This man of the prodigious mind is primarily human and involved.

W. G. BIGELOW, M.D.

Surgery of the Small Intestine. Richard L. Nelson, Lloyd M. Nyhus. 592 pp. East Norwalk, Conn: Appleton-Century-Crofts. 1986. $110.00.

THIS WORK REPRESENTS a unique contribution to the field of gastrointestinal surgery, and the editors are to be complimented for providing us with a comprehensive text that deals with an often neglected subject; the small intestine. Our understanding of digestive physiology, intestinal motility, and gut hormones has been greatly expanded in recent years. This new knowledge has fostered a scientific and rational approach to the patient with intestinal disorders, and furthermore has facilitated the development of new and innovative surgical techniques for the management of serious gastrointestinal and genitourinary problems. The editors of *Surgery of the Small Intestine* have brought together an outstanding group of authors from diverse backgrounds and disciplines, with the final product being a state-of-the-art examination of small bowel physiology, pathophysiology, and treatment of associated surgical diseases.

The book is appropriately divided into nine sections with a total of 43 chapters. In addition, there are selected "Special Comments" following several chapters. These abbreviated discussions are focused on specific issues and add clarity and perspective to selected subjects. The detailed history at the beginning of the book is both stimulating and informative, and sets the stage for the elaborate review of small bowel anatomy and physiology that follows. The final chapter in this section deals with the metabolic consequences of ileal resection, a subject of vital importance to all general surgeons. The major disorders affecting the small bowel, in both pediatrics and adult populations, are reviewed in great detail in subsequent chapters. In addition, topics of considerable current clinical and investigative interest are explored, including small bowel transplantation, radiation enteritis, ileoanal pullthroughs, the use of ileal conduits in urology, and surgery for morbid obesity. Each chapter addresses the pertinent issues in terms of physiology and pathophysiology, management, and surgical options. There are several chapters devoted to technical aspects of bowel surgery, which are greatly enhanced by appropriate and well-done illustrations.

In general, the book is well written and easy to read. Drs. Nelson and Nyhus have attempted to write an authoritative text on the most diverse organ in the gastrointestinal tract. I believe they have been immensely successful. I strongly recommend this book for all students of the gastrointestinal tract, and all surgeons who have the occasion of dealing with the small bowel.

Ban the pan

...in severe post-op N&V

Compazine®

Injection 5 mg./ml.

brand of
prochlorperazine

Available in 25 mg. suppositories, too.

Do not use 'Compazine' in pediatric surgery.

©SmithKline Beckman Corporation, 1985

See brief summary of prescribing information on adjacent page.

The antiemetic physicians prescribe most*

COMPAZINE®
brand of
prochlorperazine

See complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: For control of severe nausea and vomiting

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; pediatric surgery; use in children under 2 years of age or under 20 lbs; use in children for conditions for which dosage has not been established.

Warnings: The extrapyramidal symptoms which can occur secondary to 'Compazine' may be confused with the central nervous system signs of an undiagnosed primary disease responsible for the vomiting, e.g., Reye's syndrome or other encephalopathy. The use of 'Compazine' and other potential hepatotoxins should be avoided in children and adolescents whose signs and symptoms suggest Reye's syndrome.

May cause tardive dyskinesia in some patients on neuroleptic (antipsychotic) therapy, usually long-term. This syndrome consists of potentially irreversible, involuntary dyskinetic movements. The risk of tardive dyskinesia and likelihood of irreversibility are thought related to duration of treatment and total cumulative dose of neuroleptic drugs.

Use in patients with bone marrow depression only when potential benefits outweigh risks. Patients who develop a hypersensitivity reaction (e.g., blood dyscrasias or jaundice) to a phenothiazine generally should not be reexposed to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Prochlorperazine may intensify or prolong the action of other C.N.S. depressants.

Use in pregnancy is not recommended except in cases so serious and intractable that, in the physician's judgment, drug intervention is required and potential benefits outweigh possible hazards. There have been instances of prolonged jaundice, extrapyramidal signs, hyperreflexia or hyporeflexia in newborn infants whose mothers received phenothiazines. There is evidence that phenothiazines are excreted in the breast milk of nursing mothers.

Precautions: The antiemetic action of 'Compazine' may mask the signs and symptoms of overdosage of other drugs and may obscure the diagnosis and treatment of other conditions such as intestinal obstruction, brain tumor and Reye's syndrome (See Warnings). Postoperative aspiration of vomitus has occurred in a few surgical patients who received prochlorperazine as an antiemetic. When used concomitantly with cancer chemotherapeutic drugs, may obscure vomiting as a sign of these agents' toxicity. Deep sleep and coma have been reported with prochlorperazine, usually with overdosage.

Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent *in vitro*, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis.

Permanently stop neuroleptic therapy if neuromuscular reactions occur in pregnant women or in children.

In children with acute illnesses or dehydration, use only under close supervision. Avoid high doses and parenteral administration when cardiovascular system is impaired since hypotension has occurred. Use cautiously in patients with glaucoma. Use with caution in persons who will be exposed to extreme heat since phenothiazines may interfere with thermoregulatory mechanisms. Phenothiazines can diminish the effect of oral anticoagulants. Phenothiazines can produce alpha-adrenergic blockade. Thiazide diuretics may accentuate orthostatic hypotension that may occur with phenothiazines. Antihypertensive effects of guanethidine and related compounds may be counteracted when phenothiazines are used concomitantly. Concomitant administration of phenothiazines with propranolol results in increased plasma levels of both drugs and may also precipitate phenytoin toxicity. Phenothiazines may lower the convulsive threshold; dosage adjustments of anticonvulsants may be necessary. Presence of phenothiazines may produce false positive phenylketonuria (PKU) test results. Patients should not receive 'Compazine' 48 hours before or 24 hours after myelography with the contrast medium metrizamide.

Adverse Reactions: Drowsiness, dizziness, amenorrhea, blurred vision, skin reactions, Hypotension. Cholestatic jaundice, leukopenia, agranulocytosis. Fatty changes in the liver have been observed in a few patients who died while receiving the drug (no causal relationship has been established). Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, tardive dyskinesia, and a variant, tardive dystonia. Contact dermatitis is a possibility if 'Compazine' Injection (solution) inadvertently gets on hands or clothing.

Other adverse reactions reported with 'Compazine' or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., severe hypotension in mitral insufficiency or pheochromocytoma). Grand mal and petit mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat and organophosphorus insecticides; dryness of mouth, nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, ejaculatory disorders/impotence, priapism, atonic colon, urinary retention, miosis and mydriasis; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; pancytopenia, thrombocytopenic purpura, eosinophilia, hemolytic anemia, aplastic anemia; biliary stasis; hyperglycemia, hypoglycemia, glycosuria, lactation, galactorrhea, gynecomastia, menstrual irregularities, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema; angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; mild fever after large I.M. doses; increased appetite; increased weight; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; neuroleptic malignant syndrome, which may be fatal; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits.

EKG changes have been reported. Discontinue long-term, high-dose therapy gradually.

Note: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported.

Supplied: Tablets—5, 10 and 25 mg., in bottles of 100; Spansule® capsules—10, 15 and 30 mg., in bottles of 50; Injection—5 mg./ml. in 2 ml. ampuls, 10 ml. vials and 2 ml. disposable syringes; Suppositories—2½, 5 and 25 mg.; Syrup—5 mg./5 ml.; Single Unit Packages of 100 (intended for institutional use only)—5 and 10 mg. tablets; 10, 15 and 30 mg. 'Spansule' capsules.

If detected early, the cure rate for colorectal cancer is very high.

It can be as high as 75%.

Because we now know how to detect it early. And we know how to fight it once we detect it.

There are three simple checkup guidelines for men and women without symptoms.

One, get a digital exam every year. This is recommended for everyone over 40.

Two, get a stool blood test every year if you are over 50.

Three, after two initial negative tests one year apart, get a procto exam every three to five years if you are over 50.

These guidelines are the best protection against colorectal cancer you can have.

If you're not over 50, please give this information to friends and loved ones who are.

In any case, please help spread the word.

Good news doesn't always travel fast.

CANCER
SOCIETY®

Get a checkup. Life is worth it.

Letters to the Editor

December 1, 1986

Dear Editor:

In "Continuous Venous Oximetry in Surgical Patients" (Ann Surg 1986; 203:329–333.), Dr. Nelson has shown us a strong negative correlation between venous oxygen saturation (SvO_2) and the oxygen utilization coefficient (OUC). He has mathematically manipulated the Fick equation to show that "the determinants of SvO_2 are the components of oxygen delivery (DO_2) and oxygen consumption (VO_2)." Although the mathematics are not precisely correct, as they ignore the effect of dissolved gases, the relationship $SvO_2 = 1 - VO_2/DO_2$ is shown. Since VO_2/DO_2 is the definition of OUC, we see that $SvO_2 = 1 - OUC$. Therefore, the relationship shown in Figure 3D is mathematically ordained, and not the result of independent observations. Thus, any implication of a physiologic link (always risky with regression modeling) between SvO_2 and OUC that is based on those mathematically related observations is inappropriate. Perhaps, instead of concentrating on the closeness of the relationship, the author should have discussed the possible explanations for the deviation in Figure 3D from the mathematically predicted $y = 1 - x$. In any case it would appear that Dr. Nelson's conclusion that "SvO_2 does not correlate highly with the individual determinants of oxygen transport but rather correlates with the oxygen utilization coefficient and therefore reflects the overall balance between oxygen consumption and delivery" is not based on independent clinical observations. Regardless of the attractiveness of that hypothesis, the data in Dr. Nelson's study do not warrant that conclusion.

In spite of our disagreement with the analytic technique, we agree with Dr. Nelson's appraisal of the accuracy of mixed venous oximetry with the equipment described and of the clinical use of that measurement in a variety of critical care and intraoperative situations.

DAVID A. PAULUS, M.D.
RICHARD F. DAVIS, M.D.
Gainesville, Florida

January 20, 1987

Dear Editor:

Drs. Paulus and Davis are correct in their observations regarding the article "Continuous Venous Oximetry in Surgical Patients" (Ann Surg 1986; 203:329–333.). They point out that the contribution of dissolved oxygen to arterial and mixed venous oxygen content was ignored in the assumption that $SvO_2 = 1 - OUC$ (oxygen utilization coefficient). The dissolved oxygen content in blood (assuming reasonable hemoglobin concentration and arterial oxygen tension of less than 200 torr: both valid in these patients) is approximately 2% of total arterial content and 1% of mixed venous content. In conditions of hypoxemia and normal hemoglobin concentration, the contributions of dissolved oxygen are even less. These are negligible amounts with no clinical significance.

The derivation of the relationship $SvO_2 = 1 - OUC$ was presented in the discussion section of the article. Drs. Paulus and Davis are correct in noting that the relationship is "mathematically ordained." The question is can this link be clinically useful to the critical care surgeon?

OUC was calculated from arterial and mixed venous blood specimens, measurement of hemoglobin concentration, and thermodilution cardiac output. Since both hemoglobin and cardiac output can be factored out of the equation, the relationship is $OUC = SaO_2 - SvO_2/SaO_2$. Thus, continuous *in vivo* measurement of SvO_2 was compared with intermittent *in vitro* measurement of the determinants of SvO_2 (and the assumption that SaO_2 was high). What was shown in the article was that SvO_2 displayed continuously correlates closely with $1 - OUC$. Calculation of OUC by measurement of cardiac output, hemoglobin concentration, arterial and mixed venous oxygen saturation, and calculation of oxygen delivery and consumption requires both time and laboratory resources. If it is accepted that OUC is a useful means of assessing the oxygen supply–demand balance (a point not addressed in the article), then SvO_2 is a useful online monitor.

It is important to note that in critically ill surgical patients, a change in SvO_2 cannot be attributed reliably to any of the individual determinants of either oxygen delivery or oxygen consumption, a point often mistaken when reviewing other reports on this subject.

I thank Drs. Paulus and Davis for their interest.

LOREN D. NELSON, M.D.
Miami, Florida

January 20, 1987

Dear Editor:

Drs. Mackie, Hulks, and Cuschieri (Ann Surg 1986; 204:537–542) present evidence that confirms that gastric emptying is abnormal in patients with bile vomiting and conclude, like Toye and Alexander-Williams,[1] that altered gastric emptying is the cause of bile vomiting. We would submit that this study merely confirms an association of abnormal gastric emptying with bile vomiting, and this does not prove that the association is causal. A considerable amount of evidence leads us to believe that we should look elsewhere for the cause of bile vomiting; at least in a proportion of cases.

Bile vomiting occurs predominantly in patients who have had surgery for benign peptic ulcer. Such individuals are known to have a high prevalence of gastroesophageal reflux and esophagitis,[2] and abnormal gastric emptying is a common finding in patients with reflux.[3] The repeated effortless regurgitation of severe gastroesophageal reflux can be misinterpreted as vomiting by patient and clinician alike, and we have recent experience of two patients initially treated unsuccessfully for bile vomiting who became asymptomatic after effective fundoplication.

We are currently engaged in a study of all patients who have had surgery for bile vomiting in this department in the last 10 years, to determine the extent to which gastroesophageal reflux may have been responsible for their symptoms. Examination of the records of 25 such patients has shown that at least 10 (40%) had endoscopic signs of esophagitis before remedial surgery and four of these 10 had complications of esophagitis: two Barrett's esophagus and two esophageal strictures. Clinical and endoscopic follow-up is as yet incomplete, but we believe that these findings suggest strongly that the symptoms of a significant proportion of patients with "bile vomiting" are in fact due to gastroesophageal reflux.

The results of surgery for bile vomiting are less than ideal in most series,[4] and Ritchie has reported recently[5] that 35% of his patients continued to "vomit" after operation although the fluid disgorged was no longer bile stained. It would therefore be most interesting to know whether Mr. Mackie's patients had signs of gastroesophageal reflux on endoscopy or pH monitoring and to what extent his patients' symptoms have been relieved by treatment.

It is possible that in some patients grossly impaired gastric emptying could exacerbate gastroesophageal reflux. We suggest, however, that a careful assessment of gastroesophageal continence should be made before laying the blame for bile vomiting on delayed gastric emptying alone.

February 23, 1987

Dear Editor:

We appreciate the comments made by Mr. Flook et al. and confirm their view that esophagitis is a frequent accompaniment of bile vomiting, although we would dispute their contention that gastroesophageal reflux is the dominant mechanism responsible for bile vomiting. We have looked at our series of 97 patients with severe bile vomiting referred to AC over the past 17 years for remedial surgery. Biopsy-proven esophagitis was documented in 29-patients.

What is undeniable is that bile vomiting must be preceded by enterogastric reflux. This is usually present in patients after gastric surgery (excluding highly selective vagotomy) whether they vomit bile or not. Our recent study (Ann Surg 1986; 204:537–542) has demonstrated that the gastric emptying of this refluxate is delayed only in those patients who vomit bile. This is an undeniable fact that any other armchair hypothesis has to take into consideration. One could, indeed, argue that gastric retention would favor gastroesophageal reflux at least in some of these patients. Equally, however, the repeated vomiting may cause both the esophagitis and the gastroesophageal incompetence.

The suggestion made by Mr. Flook et al. that these patients should be investigated with pH monitoring is based on a false premise of "alkaline mucosal damage." We have studied 17 patients with bile vomiting and endoscopically proven esophagitis and have encountered "alkaline esophagitis" (reflux episodes of pH > 7.5) in only one patient; all the other 16 exhibited a normal pH profile in the lower esophagus during ambulatory 24-hour pH monitoring. These patients have presumably "neutral reflux" that cannot be detected by pH monitoring, and the damage may well be related to specific components within the refluxate (lysolecithin, bile salts, trypsin, *etc.*) rather than its alkalinity. In this respect we would suggest that reflux alkaline esophagitis is a myth.

A. CUSCHIERI
Dundee, Scotland

December 30, 1986

Dear Editor:

The paper, "An Analysis of Survival and Treatment Failure Following Abdominoperineal and Sphincter-saving Resection in Dukes' B and C Rectal Carcinoma. A Report of the NSABP Clinical Trials" by Drs. Wolmark and Fisher, in *Annals of Surgery* 1986; 204:480–489, contains a serious misimplication that requires correction.

The authors conclude in their abstract: "The data provide the first evidence from a randomized prospective clinical trial that sphincter-saving resection is not associated with attenuated survivorship or an increased incidence of treatment failure." Inherent in this statement is the implication that the surgical therapies of abdominoperineal excision or sphincter-saving resection of the rectum were randomized therapies. This was *not* the case, and hence this conclusion is *not* justified from their data. The cited reference in the current paper, describing ". . . in greater detail, protocol design and patient accession," does not define the operative conduct or protocol. Rather, it simply states "Patients with rectal tumors were treated with either anterior resection or abdominoperineal resection with the operative conduct determined by the protocol."[1] No further information is given as to how these two therapies were selected for patients from a larger undefined cohort.

To us as readers, this is a highly selected group of patients, who were legitimately randomized to adjuvant therapies after their surgical procedure; *however*, they cannot form the basis of a study as currently presented. The data apparently reflect a small part of the 85 Principle Investigator's experience, with less than one patient/year/investigator entered. The reader is not given information as to what factors, either rigid criteria or biases, determined which procedure was performed.

The misimplication that the surgical therapies were randomized was pointed out by two discussants of the paper (pp. 488–489), but despite this still remains in the text as presented in the Journal. The "abstract reader" or "skimmer" is left with the implication that this study evaluates these two operative methods in a randomized fashion. This implication is erroneous and should be corrected.

The original question posed by this randomized trial was the role of adjuvant therapy in patients after either of these surgical procedures. Randomization was performed after "curative resection." The authors have published five papers to date without addressing this primary question. Why? Randomized trials are an essential investigative method for testing therapeutic options; surely, the primary question should be addressed first. Additional information, such as data on the natural history of the disease, is often well documented in such studies because the patients are carefully followed and evaluated, but should be presented as secondary information.

The current paper does a serious disservice to prospective randomized clinical trials. Papers such as these are worthy of publication when presenting clinical experience. However, this paper presents no more than that, and should not masquerade as a randomized trial of two surgical therapies.

J. MICHAEL HENDERSON, F.R.C.S.
MICHAEL H. KUTNER, P.H.D.
Atlanta, Georgia

February 10, 1987

Dear Editor:

We are dismayed by Dr. Henderson and Kutner's assertion that we did not sufficiently emphasize the nature of the randomization in our reported study. The NSABP clinical trials assessing adjuvant therapy in colorectal cancer are well known. In fact, they are the largest clinical trials that have thus far been carried out in attempting to determine the utility of adjuvant therapy. Surgeons in particular are conversant with our studies since the majority of the 2500 patients randomized have been entered by surgeons. The specific aims of these studies as well as the randomization schemata are familiar to the majority of surgeons interested in colorectal cancer. As a consequence, the confusion expressed by Drs. Kutner and Henderson is difficult to understand.

Drs. Henderson and Kutner support their allegation by quoting a statement from our abstract: "the data provided the first evidence from a randomized prospective clinical trial that sphincter-saving resection is not associated with attenuated survivorship or an increased incidence of treatment failure." It is unclear why they failed to appreciate the statement in the abstract indicating that the analysis was derived from a randomized prospective clinical trial "designed to ascertain the efficacy of adjuvant therapy in rectal carcinoma (protocol R-01)." To dispel any potential confusion as to what the nature of the randomization was, a further description appeared in the introduction. We believe that the statement made was succinct and, accordingly, we reproduce it verbatim:

> In an effort to resolve some of the biologic and practical disputations surrounding the efficacy of sphincter-saving operations, it was considered appropriate to evaluate the data from the randomized prospective rectal cancer trial of the National Surgical Adjuvant Project for Breast and Bowel Cancer (NSABP). This study was primarily designed to evaluate the utility of adjuvant chemotherapy and radiotherapy following curative resection for Dukes' B and C cancer. Although the original specific aims of the study were not formulated to compare treatment failure and survival in patients treated with sphincter-saving resection and abdominoperineal resection, nonetheless a large patient cohort was available in whom the two operations were performed without specific protocol-determined selection bias. Despite this limitation, data were derived from patients treated with either procedure who were entered in a randomized prospective manner albeit not specifically for the end points considered in this analysis.

Further, to remove any doubt relative to the methodology it was pointed out that protocol R-01 consisted of "a randomized prospective clinical trial designed to determine the utility of adjuvant therapy in patients with carcinoma of the rectum." The nature of the study was further specified: "randomization was effected to three therapeutic categories: (1) no further treatment following curative resection, (2) postoperative radiotherapy or (3) postoperative chemotherapy consisting of 5-fluorouracil, MeCCNU (semustine) and vincristine."

Drs. Henderson and Kutner emphasize that two discussants of the oral presentation of the data (not the manuscript) alluded to the fact that randomization was not carried out between two operative options. It is our contention that the discussants had a clear understanding of the randomization procedure and, accordingly, for Drs. Kutner and Henderson to suggest that a "misapplication" had taken place is inappropriate. Drs. Kutner and Henderson elect to ignore the response made to the discussants' comments. Are Drs. Henderson and Kutner so unfamiliar with the state of the art in randomized prospective colorectal trials that they were actually mislead into assuming that a study had been done in which patients were randomized to sphincter ablation or sphincter preservation? In those few heroic attempts made to conduct such a study, accrual was nothing short of disastrous. Such a randomized prospective trial currently cannot be carried out nor is it likely that circumstances will arise to enable implementation of such a study in the foreseeable future. Given these constraints, we are insistent that our methodology represents the most accurate evaluation of the two operative interventions. Drs. Henderson and Kutner's confusion relative to the nature of this study is even more difficult to understand when one considers the second component of our investigation. We assessed disease-free survival and survival relative to the extent of margins achieved with anterior resections. To suggest that this analysis could be misconstrued as a study in which patients were randomized *a priori* to receive margins of <2 cm, 2–5 cm, and >5 cm challenges the imagination.

We take objection with the statement that patients who were entered into our randomized prospective clinical trial cannot form the basis of an analysis assessing sphincter-saving operations and abdominoperineal resections. We are perplexed by the logic in the assertion that natural history data derived from a randomized prospective trial should be presented only after the primary specific aims of the trial have been answered. It is our contention that these two goals are not mutually exclusive and both are worthy of longitudinal assessment and follow-up. Indeed, natural history information can be extremely useful in identifying discriminants for assessing interactions with treatment in proportional hazards models.

The suggestion that the data presented in our paper fall under the rubric of "clinical experience" is unworthy. Despite the fact that this trial did not randomize patients between sphincter-saving operations and abdominoperineal resections, the data were, nonetheless, derived from a prospective randomized trial. As with all NSABP trials quality control was carefully monitored and strictly enforced. Methodology was used to control for imbalances due to confounding variables. The data were controlled for Dukes' class, nodal status, and adjuvant therapy; no significant imbalances were observed with respect to age, preoperative CEA, or proportion of lumen encircled by tumor. To equate the quality of data derived from this prospective clinical trial with that of clinical experience consisting of anecdotal retrospective analyses using uncontrolled historic or concomitant nonrandomized controls is inappropriate. If Drs. Henderson and Kutner are perturbed by our methodology and relegate our data to the level of clinical experience, they must be chagrined at the plethora of anecdotal retrospective uncontrolled studies that constitute the mainstay of our most esteemed surgical journals.

Finally, it is laudable on the part of Drs. Kutner and Henderson to champion the lot of the "abstract reader" or "skimmer" and to protect him from the alleged misperception to be derived from our study. This posture raises philosophical and conceptual issues as to what constitutes the appropriate form of presenting data for publication in a journal of the calibre of the *Annals of Surgery*. Should one cater to the reader who peruses an occasional manuscript with half-hearted interest and attenuated concentration or should the manuscript be written for the surgeon who is able to review the paper in a critical and objective fashion? If favoring the latter approach constitutes a disservice to clinical trials, then we admit our guilt.

NORMAN WOLMARK, M.D.
BERNARD FISHER, M.D.
Pittsburgh, Pennsylvania

December 20, 1986

Dear Editor:

I was dismayed to read the study "EKG Guided Placement of Subclavian CVP Catheters Using J-Wire" (Ann Surg 1986; 204:673–676). The technique described is not only unnecessary but has significant potential for iatrogenic harm.

First of all, appropriate placement of central venous catheters can usually be determined clinically by a knowledge of surface anatomy and its relation to intrathoracic structures. The entry of the superior vena cava into the right atrium corresponds closely with the sternomanubrial joint (angle of Louis), which is nearly always palpable, or may be slightly caudad to the sternomanubrial joint within one intercostal space. The length of catheter necessary to traverse this distance can be easily estimated by realizing the course of the subclavian vein as it passes from the infraclavicular area to the mediastinum. I have personally used this technique for many years with good results.

Secondly, central venous catheters are often placed in patients with significant underlying problems, such as electrolyte imbalance, sepsis, ischemic heart disease, or cardiomyopathy, in which case the endocardium may be irritable and predisposed to complications thereof.

The authors' technique of manipulating central venous guidewires until arrhythmias were elicited is, to myself, both unnecessary and fraught with potential complications, especially when other reliable guides such as surface anatomy are available. The inherent arrhythmogenicity of central venous guidewires should encourage us to avoid their placement in the heart rather than purposefully seek it.

MICHAEL SWANSON, D.O.
Springfield, Missouri

February 20, 1987

Dear Editor:

Dr. Swanson's concerns are valid and his initial reaction to our technique understandable. We should look closely at the advantages and disadvantages of any new technique before considering its use in our own practice.

The advantages of the guidewire technique described in our article are that the presence of atrial arrhythmia is a reliable index of catheter tip location, resulting in 100% correct placement when present. The problem with unmonitored catheter placement is not the length of catheter, which can be approximated from surface anatomy, but the possibility of aberrant location, usually in the internal jugular vein.[1] Aberrant catheter location has been shown to produce incorrect CVP readings,[2] and can thus frustrate the basic reason for placing the catheter in the first place.

The main disadvantage of this technique is the potential for serious arrhythmia. Our current experience in 84 patients with significant ischemic heart disease confirms that of invasive cardiologists, the actual rate of morbidity caused by arrhythmia from intracardiac catheters and guidewires is surprisingly low.[3] This unexpected result perhaps renders this procedure more benign than it may appear at first sight.

In common with most procedures, the success rate in CVP catheter placement is of course operator dependent, and we would suggest consideration of this technique only for those physicians dissatisfied with their current results. Thus, not all physicians will have use for this technique, and those who do should bear in mind the importance of EKG monitoring and withdrawal of the guidewire if ventricular arrhythmia should occur.

DAVID S. STARR, M.D.
Youngstown, Ohio

January 20, 1987

Dear Editor:

I would like to offer a few remarks concerning John Porter's article in which he states that reverse vein bypass grafts to distal vessels are superior to or equivalent to *in-situ* bypass grafts for patency and for vein utilization.

Dr. Porter continues to champion the reverse vein bypass graft and he now represents a minority view. His studies are elegant and must cause those of us who enthuse over *in-situ* grafting to keep a close eye on his long-term results. I switched to *in-situ* grafting in 1981 and have used a retrograde valvulotome for performing these grafts. This valvulotome is passed up the saphenous vein from the ankle to the groin without exposing the entire length of the saphenous vein. On withdrawal the valves are instantaneously incised, making this part of the operation very rapid. My cases are followed carefully and 4-year patency rates using the life table method are equivalent to those of Leather. In my hands at least, bypasses to the ankle using the reverse technique have not been feasible.

Be that as it may, and accepting Dr. Porter's thesis and his data, I must still quarrel with his conclusion in the final paragraph of his paper: "surgeons who achieve comparable results in their own practices should feel no pressure to switch to ISVB because of presumed superiority of the latter technique." Were the *in-situ* technique truly more complicated than the reverse technique, and if the results are truly equal, then Dr. Porter's point would be well taken. However, in point of fact, anyone who has been brought up on the *in-situ* technique finds it far simpler to do than the reverse technique. I suspect, then, that new surgeons, exposed to the *in-situ* technique, will also "feel no pressure" to switch to reverse vein grafting because of the presumed equivalency of the latter procedure.

In short, if the results are equal, why not choose the easier, *in-situ* technique?

GEORGE D. LEMAITRE, M.D.
Andover, Massachusetts

April 15, 1987

Dear Editor:

We are honored to reply to the points raised by Dr. LeMaitre regarding reversed *versus in situ* vein grafts. The author makes several statements in his letter including: (1) we, and others who perform reversed vein grafts, "represent a minority view," (2) the author has been unable to achieve satisfactory results with reversed vein bypass to the ankle, and (3) Dr. LeMaitre believes that anyone who has performed both techniques will find the *in situ* bypass easier to perform.

We are pleased that the author appears to accept our data that demonstrate at least equivalent patency figures for *in situ* and reversed bypass. We are not prepared to comment on the percentage of vascular surgeons in the United States using reversed or *in situ* grafts, as we have no specific data in this area. Likewise, we have no comment regarding the author's inability to achieve reversed vein grafts to the ankle level. This technique is routinely satisfactory for us and others who use the reversed vein technique.

With regard to the relative ease of performing either operation, we have several comments. It is our belief that any vein that can be used for *in situ* bypass can also be used with reversed technique. The converse of this statement, however, is not true. *In situ* bypass requires an intact greater saphenous vein. This means that the *in situ* operation must be confined to patients whose legs were not operated on previously. It is easy to understand the perception that the technique is easier if one confines operations exclusively to this "best case" patient group. In the patient group described in our paper, 33% of patients did not possess an intact ipsilateral greater saphenous vein, and would not have been eligible for *in situ* bypass. All these patients had successful revascularization using reverse technique. Adherence to the *in situ* technique automatically eliminates this important patient group, which in our experience is increasing in size, partly due to increasing numbers of patients referred after failed *in situ* bypass. Limiting lower extremity bypass to the *in situ* technique thus may be viewed from one aspect as a means to guarantee improved operative results by eliminating from consideration the group of patients (those previously operated on) in whom it will be most difficult to achieve successful lower extremity revascularization.

These considerations aside, however, it remains clear from abundant published evidence that equally skilled surgeons may be expected to obtain equivalent results with reversed or *in situ* vein grafts. Currently we are unaware of any evidence indicating clear superiority of one technique over the other. However, the reversed vein graft technique is applicable to significantly more patients, including the difficult patient group with failed previous bypasses. We are honored that Dr. LeMaitre found our article sufficiently provocative to warrant comment.

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

- Title page
- Abstract and key words
- Text
- Acknowledgments
- References
- Tables: each table, complete with title and footnotes, on a separate page
- Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

Methods: Describe your selection of the observational or experimental subjects (patients or experimental animals, including controls) clearly. Identify the methods, apparatus (manufacturer's name and address in parentheses), and procedures in sufficient detail to allow other workers to reproduce the results. Give references to established methods, including statistical methods; provide references and brief descriptions of methods that have been published but are not well known; describe new or substantially modified methods, give reasons for using them, and evaluate their limitations.

When reporting experiments on human subjects, indicate whether the procedures followed were in accord with the ethical standards of the Committee on Human Experimentation of the institution in which the experiments were done or in accord with the Helsinki Declaration of 1975. When reporting experiments on animal subjects, indicate whether the institution's or the National Research Council's guide for the care and use of laboratory animals was followed. Identify precisely all drugs and chemicals used, including generic name(s), dosage(s), and route(s) of administration. Do not use patients' names, initials, or hospital numbers.

Include numbers of observations and the statistical significance of the findings when appropriate. Detailed statistical analyses, mathematical derivations, and the like may sometimes be suitably presented in the form of one or more appendixes.

Results: Present your results in logical sequence in the text, tables, and illustrations. Do not repeat in the text all the data in the tables and/or illustrations: emphasize or summarize only important observations.

Discussion: Emphasize the new and important aspects of the study and *conclusions* that follow from them. Do not repeat in detail data given in the Results section. Include in the Discussion the implications of the findings and their limitations and relate the observations to other relevant studies. Link the conclusions with the goals of the study but avoid unqualified statements and conclusions not completely supported by your data. Avoid claiming priority and alluding to work that has not been completed. State new hypotheses when warranted, but clearly label them as such. Recommendations, when appropriate, may be included.

ACKNOWLEDGMENTS

Acknowledge only persons who have made substantive contributions to the study. Authors are responsible for obtaining written permission from everyone acknowledged by name because readers may infer their endorsement of the data and conclusions.

REFERENCES

Number references consecutively in the order in which they are first mentioned in the text. Identify references in text, tables, and legends by arabic numerals (in parenthesis). References cited *only* in tables or in legends to figures should be numbered in accordance with a sequence established by the first identification in the text of the particular table or illustration.

Use the form of references adopted by the U.S. National Library of Medicine and used in *Index Medicus.* Use the style of the examples cited at the end of this section, which have been approved by the National Library of Medicine.

The titles of journals should be abbreviated according to the style used in *Index Medicus.* A list of abbreviated names of frequently cited journals is given near the end of this document; for others, consult the "List of Journals Indexed," printed annually in the January issue of *Index Medicus.*

Try to avoid using abstracts as references; "unpublished observations" and "personal communications" may not be used as references, although references to written, not verbal, communications may be inserted (in parentheses) in the text. Include among the references manuscripts accepted but not yet published; designate the journal followed by "in press" (in parentheses). Information from manuscripts submitted but not yet accepted should be cited in the text as "unpublished observations" (in parentheses).

The references must be verified by the author(s) against the original documents.

Examples of correct forms of references are given below.

TABLES

Type each table on a separate sheet: remember to double space. Do not submit tables as photographs. Number tables consecutively and supply a brief title for each. Give each column a short or abbreviated heading. Place explanatory matter in footnotes, not in the heading. Explain in footnotes all nonstandard abbreviations that are used in each table. For footnotes, use the following symbols in this sequence: *, †, ‡, §, ||, ¶, **, ††. . . . Identify statistical measures of variations such as SD and SEM.

Omit internal horizontal and vertical rules.

Cite each table in the text in consecutive order.

If you use data from another published or unpublished source, obtain permission and acknowledge fully.

Having too many tables in relation to the length of the text may produce difficulties in the layout of pages. Examine issues of the journal to which you plan to submit your manuscript to estimate how many tables to use per 1000 words of text.

The editor on accepting a manuscript may recommend that additional tables containing important backup data too extensive to be published may be deposited with the National Auxiliary Publications Service or made available by the author(s). In that event, an appropriate statement will be added to the text. Submit such tables for consideration with the manuscript.

ILLUSTRATIONS

Black-and-white illustrations and tabular material will be published free in moderate numbers. Excess illustrations, excess tabular material, and all color illustrations will be charged to the author. Submit the required number of complete sets of figures. Figures should be professionally drawn and photographed; freehand or typewritten lettering is unacceptable. Instead of *original* drawings, roentgenograms, and other material, send sharp, glossy black-and-white photographic prints, usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.). Letters, numbers, and symbols should be clear and even throughout, and of sufficient size that when reduced for publication each item will still be legible. Titles and detailed explanations belong in the legends for illustrations, not on the illustrations themselves.

Each figure should have a label pasted on its back indicating the number of the figure, the names of the authors, and the top of the figure. Do not write on the back of the figures or mount them on cardboard, or scratch or mar them using paper clips. Do not bend figures.

Photomicrographs must have internal scale markers. Symbols, arrows, or letters used in the photomicrographs should contrast with the background.

If photographs of persons are used, either the subjects must not be identifiable or their pictures must be accompanied by written permission to use the photograph.

Cite each figure in the text in consecutive order. If a figure has been published, acknowledge the original source and submit written permission from the copyright holder to reproduce the material. Permission is required, *regardless of authorship or publisher*, except for documents in the public domain.

For illustrations in color, supply color negatives or positive transparencies and, when necessary, accompanying drawings marked to indicate the region to be reproduced; in addition, send two positive color prints to assist editors in making recommendations.

LEGENDS FOR ILLUSTRATIONS

Type legends for illustrations double spaced, starting on a separate page with arabic numerals corresponding to the illustrations. When symbols, arrows, numbers, or letters are used to identify parts of the illustrations, identify and explain each one clearly in the legend. Explain internal scale and identify method of staining in photomicrographs.

ABBREVIATIONS

Use only standard abbreviations (*see* below for lists of commonly used approved abbreviations). Consult the following sources for additional standard abbreviations: [1] CBE Style Manual Committee. Council of Biology Editors style manual: a guide for authors, editors, and publishers in the biological sciences. 4th ed. Arlington: Council of Biology Editors, 1978; and [2] O'Connor M, Woodford FP. Writing scientific papers in English: an ELSE-Ciba Foundation guide for authors. Amsterdam, Oxford, New York: Elsevier-Excerpta Medica, 1975. Avoid abbreviations in the title. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

In most countries the International System of Units (SI) is standard or is becoming so. Report measurements in the units in which they were made. Journals may use these units, convert them to another system, or use both.

SUBMISSION OF MANUSCRIPTS

Mail the required number of manuscript copies in a heavy paper envelope, enclosing the manuscript copies and figures in cardboard, if necessary, to prevent bending of photographs during mail handling. Place photographs and transparencies in a separate heavy paper envelope.

Manuscripts should be accompanied by a covering letter from the author who will be responsible for correspondence regarding the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors. The letter should give any additional information that may be helpful to the editor, such as the type of article the manuscript represents in the particular journal, information on publication of any part of the manuscript, and whether the author(s) will be willing to meet the cost of reproducing color illustrations. Include copies of any permissions needed to reproduce published material or to use illustrations of identifiable subjects.

PUBLISHER'S NOTICES

CHANGE OF ADDRESS: Please allow 60 days before date of issue for change of address. Notification should include the old as well as the new address, with indication of whether the change is temporary or permanent. Please give the name of the journal.

Change of Address and Subscription correspondence for all countries except Japan should be sent to:

ANNALS OF SURGERY
Journal Fulfillment Department
Lippincott/Harper
2350 Virginia Avenue
Hagerstown, MD 21740

Correspondence about subscriptions in Japan should be sent to:

Woodbell Scope Incorporated
Mansui Building
9-18, Kanda Surugadai 2-chome
Chiyoda-ku
Tokyo 101, Japan

Copies will not be replaced without charge unless we receive a request within 60 days of the mailing in the U.S. or within 5 months in all other countries.

BUSINESS ADDRESS: Reprints, advertising, and all business communications should be addressed to:

ANNALS OF SURGERY
J. B. Lippincott Company
East Washington Square
Philadelphia, PA 19105

SAVE AND PROTECT YOUR COPIES
With Custom-Made Cases and Binders

Organize and keep copies of this publication readily available for reference with custom-made, titled cases and binders. Whichever you choose, you'll have a storage system that's durable and well organized to help protect your valuable copies from damage.

Each designed to hold a year's issues (may vary with issue sizes) • Constructed of heavy reinforced board covered with durable leather-like material with title hot-stamped in gold • Free personalization foil for indexing year • Cases V-notched for easy access • Binders have individual rods which allow issues to be fully opened for easy readability.

Cases:	1-$7.95	3-$21.95	6-$39.95
Binders:	1-$9.95	3-$27.95	6-$52.95

Be sure to indicate title in space provided below

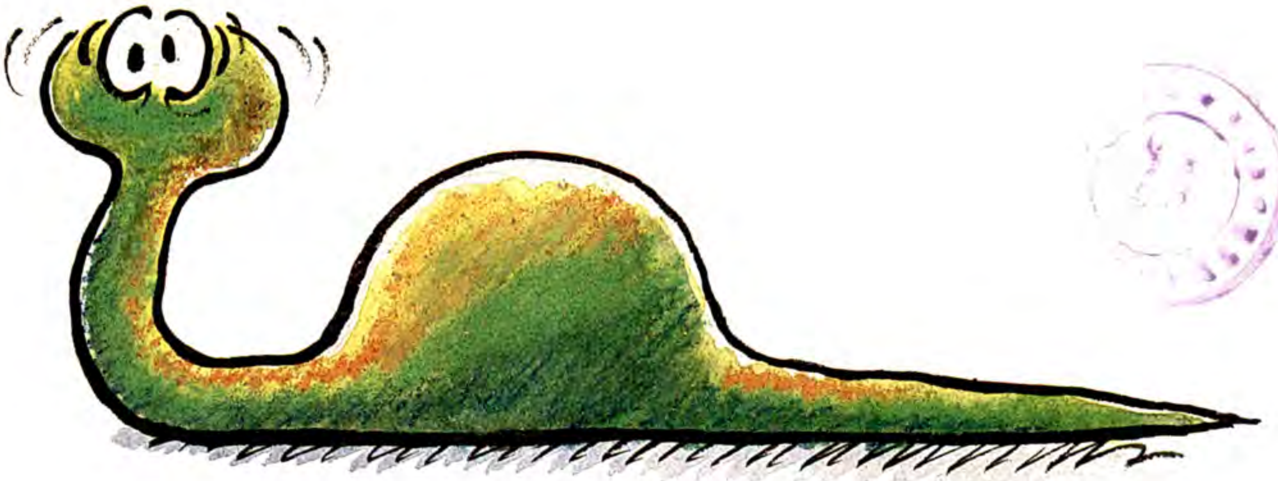
If the movement needs improvement...
Colace® or Peri-Colace®



Recommend the time-tested anticonstipants that relieve gently and reliably. Colace (docusate sodium) softens the stool and helps prevent straining…especially important for patients with anorectal disorders.

When laxative action is also needed, Peri-Colace (casanthranol and docusate sodium) both softens stools and stimulates peristalsis to correct constipation, usually overnight.

Colace and Peri-Colace offer you the flexibility of 50 mg and 100 mg capsules, syrup, or liquid. Recommend them with confidence for virtually all your adult and pediatric patients.

Gentle relief you've relied on for over 25 years

COLACE® (stool softener)

PERI·COLACE® (laxative plus stool softener)

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,[*] *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*[†] (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,[*] *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,[†] and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species[†]).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*[†]), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.[†]

[*] **NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

[†] Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

YOU CAN FIGHT CANCER BEFORE YOU GET IT.

OR AFTER YOU GET IT.

It's a lot easier to fight cancer before you get it.

Scientists estimate that up to 60% of all cancer could be prevented.

By simply making a few changes in your lifestyle.

By not getting too much sun. By not smoking cigarettes. By not overeating. And by following a diet high in fiber and low in fat.

By simply doing these few things, you could drastically reduce your risk of getting cancer.

Sure, you could still get cancer.

But why not give yourself the odds against it?

Help us keep winning.

vicodin® CIII

hydrocodone bitartrate 5 mg (Warning: May be habit forming.) with acetaminophen 500 mg

INDICATIONS AND USAGE: For the relief of moderate to moderately severe pain.
CONTRAINDICATIONS: Hypersensitivity to acetaminophen or hydrocodone.
WARNINGS
Drug Abuse and Dependence: VICODIN is subject to the Federal Controlled Substances Act (Schedule III). Psychic dependence, physical dependence and tolerance may develop upon repeated administration of narcotics; therefore, VICODIN should be prescribed and administered with the same caution appropriate to the use of other oral-narcotic-containing medications.
Respiratory Depression: At high doses or in sensitive patients, hydrocodone may produce dose-related respiratory depression by acting directly on brain stem respiratory centers. Hydrocodone also affects centers that control respiratory rhythm, and may produce irregular and periodic breathing.
Head Injury and Increased Intracranial Pressure: The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a preexisting increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.
Acute Abdominal Conditions: The administration of narcotics may obscure the diagnosis or clinical course of patients with acute abdominal conditions
PRECAUTIONS
Special Risk Patients: VICODIN should be used with caution in elderly or debilitated patients and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, prostatic hypertrophy or urethral stricture.
Information for Patients: VICODIN, like all narcotics, may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery; patients should be cautioned accordingly.
Cough Reflex: Hydrocodone suppresses the cough reflex; caution should be exercised when VICODIN is used postoperatively and in patients with pulmonary disease.
Drug Interactions: The CNS-depressant effects of VICODIN may be additive with that of other CNS depressants. When combined therapy is contemplated, the dose of one or both agents should be reduced. The use of MAO inhibitors or tricyclic antidepressants with hydrocodone preparations may increase the effect of either the antidepressant or hydrocodone. The concurrent use of anticholinergics with hydrocodone may produce paralytic ileus.
Usage in Pregnancy: Pregnancy Category C. Hydrocodone has been shown to be teratogenic in hamsters when given in doses 700 times the human dose. There are no adequate and well-controlled studies in pregnant women. VICODIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Nonteratogenic Effects: Babies born to mothers who have been taking opioids regularly prior to delivery will be physically dependent. The intensity of the syndrome does not always correlate with the duration of maternal opioid use or dose.
Labor and Delivery: Administration of VICODIN to the mother shortly before delivery may result in some degree of respiratory depression in the newborn, especially if higher doses are used.
Nursing Mothers: It is not known whether this drug is excreted in human milk; therefore, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS
Central Nervous System: Sedation, drowsiness, mental clouding, lethargy, impairment of mental and physical performance, anxiety, fear, dysphoria, dizziness, psychic dependence, mood changes.
Gastrointestinal System: Nausea and vomiting may occur; they are more frequent in ambulatory than in recumbent patients. Prolonged administration of VICODIN may produce constipation.
Genitourinary System: Ureteral spasm, spasm of vesical sphincters and urinary retention have been reported.
Respiratory Depression: (See WARNINGS.)
DOSAGE AND ADMINISTRATION: Dosage should be adjusted according to the severity of the pain and the response of the patient. However, tolerance to hydrocodone can develop with continued use, and the incidence of untoward effects is dose related. The usual dose is one tablet every six hours as needed for pain. (If necessary, this dose may be repeated at four-hour intervals.) In cases of more severe pain, two tablets every six hours (up to eight tablets in 24 hours) may be required.

	CONSTIPATION	RESPIRATORY DEPRESSION	SEDATION	EMESIS	PHYSICAL DEPENDENCE
HYDROCODONE		X			X
CODEINE	X	X	X	X	X
OXYCODONE	XX	XX	XX	XX	XX

Blank space indicates that no such activity has been reported.

Table adapted from Facts and Comparisons (Nov.) 1984 and Catalano RB. The medical approach to management of pain caused by cancer. "Semin Oncol" 1975; 2; 379-92 and Reuler JB, et. al. The chronic pain syndrome: misconceptions and management. "Ann Intern Med" 1980; 93; 588-96.

◆ Vicodin offers: less nausea, less sedation, less constipation.

...and longer lasting pain relief–up to 6 hours.

◆ Vicodin contains hydrocodone not codeine. In one study, 10 mg. of hydrocodone alone was shown to be as effective as 60 mg. of codeine.[1]

◆ In a double-blind study, Vicodin (2 tablets), provided longer lasting pain relief than 60 mg. of codeine.[2]

Plus...

◆ Vicodin offers the convenience of CIII prescribing.

◆ Dosage flexibility–1 tablet every 6 hours or 2 tablets every 6 hours (up to 8 tablets in 24 hours).

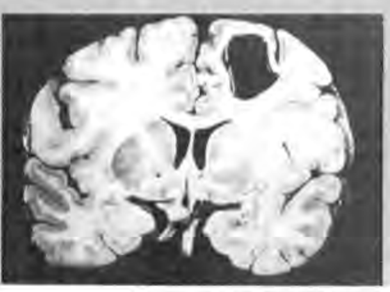
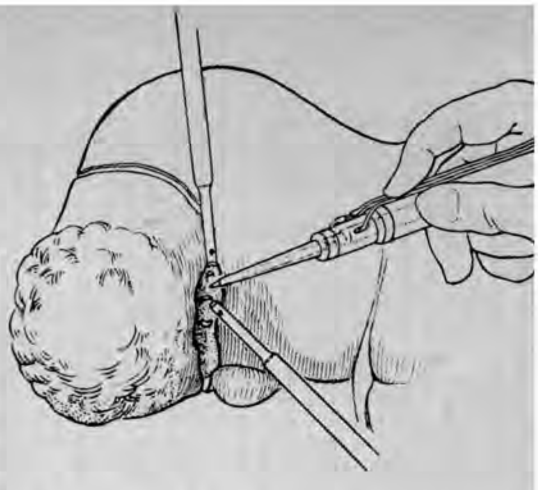
Now...the new book that shows you the role of surgical resection in the curative treatment of metastatic cancer





SURGICAL TREATMENT of METASTATIC CANCER

Edited by Steven A. Rosenberg, M.D., Ph.D.

Chief of Surgery, National Cancer Institute, Bethesda, MD.
9 contributors.

> *“For many patients with isolated visceral metastases from solid tumors, surgical resection of those metastatic deposits represents the best opportunity for cure. For patients with solitary pulmonary and hepatic metastases, up to 30% of patients may experience prolonged disease-free survival after metastasectomy. Only a small subset of patients with metastatic cancer are likely to benefit from surgical resection and identification of these patients is an important part of the application of this treatment.”*
>
> **—from the *Preface***

Taking a bold approach to treatment

Now, for the first time, here is an in-depth resource that describes the role of surgical resection in the treatment of metastatic cancer. Editor Dr. Steven A. Rosenberg, Chief of Surgery at the National Cancer Institute, and a leading figure in cancer research and treatment, poses the premise that the role of surgical resection in treating metastatic cancer has indeed been underappreciated. He and a distinguished group of contributors have designed this book to present the essential information oncologists and surgeons need to understand the value of this treatment.

Presenting a highly significant option

Detailed information is presented concerning:

- the modern understanding of the biology of the metastatic process
- up-to-date techniques for the diagnosis of lung, liver, and brain metastases
- indications for and results of the surgical resection of lung, liver, and brain metastases
- the indications for lymph node dissection in the treatment of cancer.

about 304 pages. 120 illustrations. 68 tables. 1987. $59.50

THROMBOSTAT™ (THROMBIN, USP), a trusted hemostatic aid, is now available in a pump spray form—permitting flexible and easy application. With the new THROMBOSTAT pump, you can achieve hemostasis in seconds over large body surface areas. Each depression of the pump offers an even distribution

SPRAY ON HEMOSTASIS

of THROMBOSTAT solution—allowing uniform hemostasis of the total area. The THROMBOSTAT pump is available in a convenient sterile kit that features a 20,000-unit vial of THROMBOSTAT (a practical size for procedures involving capillary bleeding), an appropriate measure of diluent, and a pump sprayer cap. The kit offers sterile packaging—permitting the entire contents to be brought directly into the sterile field. With the new THROMBOSTAT kit, it has never been simpler to control capillary bleeding.

Please see next page for brief summary of prescribing information.

THROMBOSTAT™ (THROMBIN, USP) (Bovine Origin)

Before prescribing, please see full prescribing information. A Brief Summary follows:

Thrombostat must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE: Thrombostat (Thrombin, USP) is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery solutions of Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS: Thrombostat is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING: Because of its action in the clotting mechanism, Thrombostat must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Thrombostat is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS: General: Consult the absorbable gelatin sponge product labeling for complete information for use prior to utilizing the thrombin-saturated-sponge procedure.

Pregnancy—Teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical (Bovine). It is also not known whether Thrombin, Topical (Bovine) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical (Bovine) should be given to a pregnant woman only if clearly indicated.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: An allergic type reaction following the use of Thrombostat for treatment of epistaxis has been reported. Febrile reactions have also been observed following the use of Thrombostat in certain surgical procedures but no cause-effect relationship has been established.

DOSAGE AND ADMINISTRATION: General: Solutions of Thrombostat may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc, solutions containing approximately 100 units per ml are frequently used. For this, 10 ml of diluent added to the 1000 unit package is suitable. Where bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1000 to 2000 units per ml may be required. For this the 5000 unit vial dissolved in 5 ml or 2.5 ml respectively, of the diluent supplied in the package is convenient. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate volume of diluent. In many situations, it may be advantageous to use Thrombostat (Thrombin, USP) in dry form on oozing surfaces.

Caution: Solutions should be used the day they are prepared. The solution may be used for up to 6 hours when stored at room temperature; up to 24 hours when stored under refrigeration, and, if necessary, up to 48 hours when stored frozen.

The following techniques are suggested for the topical application of Thrombostat.

1. The recipient surface should be sponged (not wiped) free of blood before Thrombostat is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the Thrombostat mixes freely with the blood as soon as it reaches the surface.
3. In instances where Thrombostat in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried Thrombostat is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place.

Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP as follows:

1. Prepare Thrombostat solution of the desired strength.
2. Immerse sponge strips of the desired size in the Thrombostat solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

Thrombostat Kit: Thrombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. The Kit may be used as follows:

1. Remove the Tyvek blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared and the pump sprayer cap inserted and seated on the Thrombostat solution vial. Note: Several strokes of the pump sprayer will be required before the Thrombostat solution is expelled.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

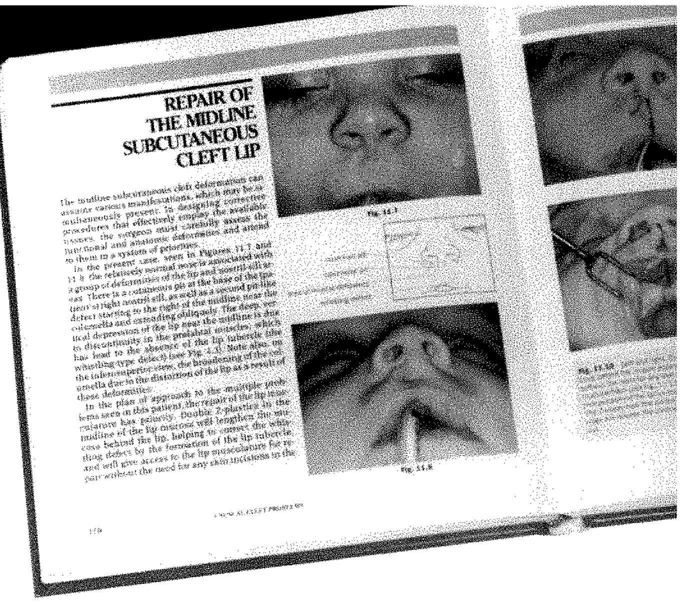
A vivid, FULL COLOR ATLAS...



REPAIR OF THE MIDLINE SUBCUTANEOUS CLEFT LIP

Techniques in CLEFT LIP, NOSE AND PALATE RECONSTRUCTION

...show you the art of reconstructive plastic surgery for children born with cleft deformities

By Donald I. Kapetansky, M.D.

Foreword by D. Ralph Millard, Jr., M.D.

250 Beautiful, full-color illustrations...

. . . show you some of the most effective and efficient procedures in use today to correct cleft deformities in children. Sequential photographs of operations show each step of repair. Clear, close-up photographs show cleft deformities from various angles to help you fully understand the patient's condition. Detailed line drawings, full-color schematic diagrams, and explanatory text accompany the photographs and clarify important aspects of the deformities and the surgical techniques employed to correct them.

Complete coverage of surgical procedures

This book is divided into four parts, each focusing on a particular type of congenital deformity. Parts I and II focus, respectively, on primary and deferred corrective procedures for unilateral and bilateral cleft lip and nose reconstruction. These sections are primarily concerned with improving the child's appearance. Part III deals with cleft palate reconstruction and pharyngeal-flap procedures. This section details surgical techniques aimed at restoring the function of the palate in speech production—without producing iatrogenic facial deformities. Two types of transverse pharyngeal-flap surgery are described in this section. Part IV deals with some unusual cleft problems and three case studies in long-term cleft reconstruction.

Considers the total perioperative picture

With 25 years of practice and more than 2500 cleft operations to his credit, the author brings a wide range of experience and an authoritative viewpoint to this work. From a concentration on techniques that require fewer staged procedures, to methods of suturing the skin, to the use of long-acting local anesthetics even with general anesthesia—you'll find a multitude of suggestions for pre- and postoperative care and interoperative planning that aim to ease the strain on children enduring multiple surgical procedures.

Management of Head and Neck Cancer
A Multidisciplinary Approach

Flexible and innovative therapies for the management of cancer patients

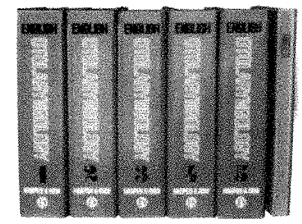
Management of Head and Neck Cancer:

A Multidisciplinary Approach

Edited by Rodney R. Million, M.D., and Nicholas J. Cassisi, M.D.
20 Contributors.

". . . a superb volume on head and neck cancer that will at once become the standard of reference . . . comprehensive, with 36 chapters ranging from the history of diagnosis and treatment of head and neck cancer . . . to such modern-day concerns as costs in management of these cancers. In style and format, in illustration and graphics, and particularly in the overall connectedness of the whole, the authors and publisher have produced a work sure to become a classic."—*The Journal of the American Medical Association* ***684 Pages. 941 Illustrations, including 43 in Full Color. 232 Tables. 1984. $99.50.***

OTOLARYNGOLOGY (Loose Leaf) 5-Volumes with Annual Revision Service



Editor-in-Chief: Gerald M. English, M.D., F.A.C.S./ 220 Contributors.

4,900 Pages. 3,600 Illustrations, 214 Tables. $400.00 (includes first year new page service). Add $10 for 4th class postage and handling. 10% discount on purchase price when payment accompanies order.

Until now,

there has been no definitive treatment for stage II postmenopausal patients…

Chemotherapy

Contribution of cytotoxics uncertain; potentially serious/intolerable side effects

No therapy

Important new data[1] rule out no therapy

Today there is.

10 MG TABLETS

Nolvadex®

TAMOXIFEN CITRATE

Adjuvant Monotherapy

Now, the treatment of choice

A recent National Institutes of Health consensus report states that following surgery, "Tamoxifen [NOLVADEX] should now be regarded as standard therapy for postmenopausal patients with positive axillary lymph nodes and positive hormone receptor status."[1]

NOLVADEX increases disease-free time[2-5] by delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer ($T_{1\text{-}3}$, N_1, M_0). Moreover, NOLVADEX improves overall survival, with a 34% reduction in risk of mortality, as observed in the NOLVADEX Adjuvant Trial Organization (NATO) study.[4] This treatment is extremely well tolerated by patients[2-5]; in fact, one double-blind, placebo-controlled study demonstrated a NOLVADEX side effects profile similar to placebo.[2] And, since NOLVADEX has a mild side effects profile and is easy to administer, patients are afforded a better quality of life. NOLVADEX—today's promising breast cancer therapy for the postmenopausal woman—in the adjuvant setting and in metastatic disease.

Please see next page for brief summary of prescribing information.

NOLVADEX®

TAMOXIFEN CITRATE

BRIEF SUMMARY

INDICATIONS AND USAGE: NOLVADEX is effective in the treatment of metastatic breast cancer in postmenopausal women. Available evidence indicates that patients whose tumors are estrogen receptor positive are more likely to benefit from NOLVADEX therapy.

NOLVADEX is effective in delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T1-3, N1, M0). The estrogen and progesterone receptor values may help to predict whether NOLVADEX therapy is likely to be beneficial. In some NOLVADEX adjuvant studies, most of the benefit to date has been in the subgroup with 4 or more positive axillary nodes.

CONTRAINDICATIONS: None known.

WARNINGS: Pregnancy Category D: NOLVADEX may cause fetal harm when administered to a pregnant woman. Individuals should not become pregnant while taking NOLVADEX. Effects on reproductive functions are expected from the antiestrogenic properties of the drug. In reproductive studies in rats at dose levels equal to or below the human dose, nonteratogenic developmental skeletal changes were seen and were found to be reversible. In addition, in fertility studies in rats and in teratology studies in rabbits using doses at or below those used in humans, a lower incidence of embryo implantation and a higher incidence of fetal death or retarded in utero growth were observed, with slower learning behavior in some rat pups. The impairment of learning behavior did not achieve statistical significance in one study, and, in another study where significance was reported, this was by comparing dosed animals with controls of another study. Several pregnant marmosets were dosed during organogenesis or in the last half of pregnancy. No deformations were seen and although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. There are no adequate and well controlled studies in pregnant women. There have been reports of spontaneous abortions, birth defects, fetal deaths, and vaginal bleeding. If this drug is used during pregnancy or the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Ocular changes have been reported in a few patients who, as part of a clinical trial, were treated for periods greater than one year with NOLVADEX at doses at least four times the highest recommended daily dose of 40 mg. The ocular changes consist of retinopathy and, in some patients, there are also corneal changes and a decrease in visual acuity.

In addition, a few cases of ocular changes including visual disturbance, corneal changes, and/or retinopathy have been reported in patients treated with NOLVADEX at recommended doses. It is uncertain if these effects are due to NOLVADEX.

As with other additive hormonal therapy (estrogens and androgens), hypercalcemia has been reported in some breast cancer patients with bone metastases within a few weeks of starting treatment with NOLVADEX. If hypercalcemia does occur, appropriate measures should be taken and, if severe, NOLVADEX should be discontinued.

PRECAUTIONS: General: NOLVADEX should be used cautiously in patients with existing leukopenia or thrombocytopenia. Observations of leukopenia and thrombocytopenia occasionally have been made, but it is uncertain if these effects are due to NOLVADEX therapy. Transient decreases in platelet counts, usually to 50,000-100,000/cu mm, infrequently lower, have been occasionally reported in patients taking NOLVADEX for breast cancer. No hemorrhagic tendency has been recorded and the platelet counts returned to normal levels even though treatment with NOLVADEX continued.

Laboratory Tests: Periodic complete blood counts, including platelet counts, may be appropriate.

Carcinogenesis: While no conventional bioassay has been conducted, endocrine changes in immature and mature mice were investigated in a 13-month study. Granulosa cell ovarian tumors and interstitial cell testicular tumors were found in mice receiving NOLVADEX, but not in the controls.

Mutagenesis: No genotoxic potential has been found in a battery of in vivo and in vitro tests with pro- and eukaryotic test systems with drug metabolizing systems present.

Impairment of Fertility: Fertility in female rats was decreased following administration of 0.04 mg/kg for 2 weeks prior to mating through day 7 of pregnancy. There was a decreased number of implantations, and all fetuses were found dead.

Following administration to rats of 0.16 mg/kg from days 7-17 of pregnancy, there were increased numbers of fetal deaths. Administration of 0.125 mg/kg to rabbits during days 6-18 of pregnancy resulted in abortion or premature delivery. Fetal deaths occurred at higher doses. There were no teratogenic changes in either rat or rabbit segment II studies. Several pregnant marmosets were dosed with 10 mg/kg/day either during organogenesis or in the last half of pregnancy. No deformations were seen, and, although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. Rats given 0.16 mg/kg from day 17 of pregnancy to 1 day before weaning demonstrated increased numbers of dead pups at parturition. It was reported that some rat pups showed slower learning behavior, but this did not achieve statistical significance in one study, and in another study where significance was reported, this was by comparing dosed animals with controls of another study.

The recommended daily human dose of 20-40 mg corresponds to 0.4-0.8 mg/kg for an average 50 kg woman.

Pregnancy Category D: See WARNINGS.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from NOLVADEX, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

ADVERSE REACTIONS: The most frequent adverse reactions to NOLVADEX are hot flashes, nausea and vomiting. These may occur in up to one-fourth of patients, but are rarely severe enough to require discontinuation of treatment.

Less frequently reported adverse reactions are vaginal bleeding, vaginal discharge, menstrual irregularities and skin rash. Usually these have not been of sufficient severity to require dosage reduction or discontinuation of treatment.

Increased bone and tumor pain and, also, local disease flare have occurred, which are sometimes associated with a good tumor response. Patients with increased bone pain may require additional analgesics. Patients with soft tissue disease may have sudden increases in the size of preexisting lesions, sometimes associated with marked erythema within and surrounding the lesions and/or the development of new lesions. When they occur, the bone pain or disease flare are seen shortly after starting NOLVADEX and generally subside rapidly.

Other adverse reactions which are seen infrequently are hypercalcemia, peripheral edema, distaste for food, pruritus vulvae, depression, dizziness, light-headedness and headache. There have been infrequent reports of thromboembolic events occurring during NOLVADEX therapy. Since for cancer patients in general an increased incidence of thromboembolic events is known to occur, a causal relationship to NOLVADEX remains conjectural. An increased incidence has been reported when cytotoxins are combined with NOLVADEX.

If adverse reactions are severe, it is sometimes possible to control them by a simple reduction of dosage without loss of control of the disease.

OVERDOSAGE: Acute overdosage in humans has not been reported. Signs observed at the highest doses following studies to determine LD_{50} in animals were respiratory difficulties and convulsions. No specific treatment for overdosage is known; treatment must be symptomatic.

DOSAGE AND ADMINISTRATION: One or two 10 mg tablets twice a day (morning and evening). In the three single agent adjuvant NOLVADEX studies noted above (See Clinical Pharmacology), NOLVADEX was administered for two years. The optimal duration of adjuvant therapy is not known.

HOW SUPPLIED: Tablets containing tamoxifen as the citrate in an amount equivalent to 10 mg of tamoxifen (round, biconvex, uncoated, white tablet identified with NOLVADEX 600 debossed on one side and a cameo debossed on the other side) are supplied in bottles of 60 tablets and 250 tablets. Protect from heat and light.

For your professional library **Bound volumes** of

Annals of Surgery

Long after your personal copies of ANNALS OF SURGERY have been read, shared with your office staff, used up and worn out, you can have instant access to the unique and valuable information in back issues of this distinguished journal by ordering bound volumes.

Your bound volumes give you a permanent and comprehensive reference for changes and advances in your specialty—a source that will grow and increase in usefulness over the years. Each volume features:

- *all text pages of every issue, including the complete author and title indexes*
- *no advertising—only professional, clinically pertinent material (a space-saver on your bookshelves)*
- *handsome, durable bindings in maroon buckram, with the journal name, year, and volume number imprinted in gold on the spine*

No need to return your personal copies to us, or to go to the trouble and expense of having them bound locally. We over-run copies of each issue in order to have sufficient quantities on hand. But we must tell our printer how many we need, so please let us know right away.

You must be a current subscriber to take advantage of this bound volume offer.

Use the convenient coupon to order your 1987 volumes today. They will be on their way to you shortly after the publication of the final volume issue.

Yes! Please send me the 1987 bound volumes of ANNALS OF SURGERY (65-98635/65-98643) for $49.00 U.S. ($59.00 elsewhere).

NUBAIN® IM IV SC
nalbuphine HCl

Brief Summary of Prescribing Information

INDICATIONS For the relief of moderate to severe pain. NUBAIN can also be used for preoperative analgesia, as a supplement to surgical anesthesia, and for obstetrical analgesia during labor.

CONTRAINDICATIONS NUBAIN should not be administered to patients who are hypersensitive to it.

WARNINGS Drug Dependence NUBAIN has been shown to have a low abuse potential which is approximate to that of pentazocine. When compared with drugs which are not mixed agonist-antagonists, it has been reported that nalbuphine's potential for abuse would be less than that of codeine and propoxyphene. Psychological and physical dependence and tolerance may follow the abuse or misuse of nalbuphine. Therefore, caution should be observed in prescribing it for emotionally unstable patients, or for individuals with a history of narcotic abuse. Such patients should be closely supervised when long-term therapy is contemplated. Care should be taken to avoid increases in dosage or frequency of administration which in susceptible individuals might result in physical dependence. Abrupt discontinuation of NUBAIN following prolonged use has been followed by symptoms of narcotic withdrawal, i.e., abdominal cramps, nausea and vomiting, rhinorrhea, lacrimation, restlessness, anxiety, elevated temperature and piloerection. **Use in Ambulatory Patients** NUBAIN may impair the mental or physical abilities required for the performance of potentially dangerous tasks such as driving a car or operating machinery. Therefore, NUBAIN should be administered with caution to ambulatory patients who should be warned to avoid such hazards. **Use in Emergency Procedures** Maintain patient under observation until recovered from NUBAIN effects that would affect driving or other potentially dangerous tasks. **Use in Children** Clinical experience to support administration to patients under 18 years is not available at present. **Use in Pregnancy (other than labor)** Safe use of NUBAIN in pregnancy has not been established. Although animal reproductive studies have not revealed teratogenic or embryotoxic effects, nalbuphine should only be administered to pregnant women when, in the judgement of the physician, the potential benefits outweigh the possible hazards. **Use During Labor and Delivery** NUBAIN can produce respiratory depression in the neonate. It should be used with caution in women delivering premature infants. **Head Injury and Increased Intracranial Pressure** The possible respiratory depressant effects and the potential of potent analgesics to elevate cerebrospinal fluid pressure (resulting from vasodilation following CO_2 retention) may be markedly exaggerated in the presence of head injury, intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, potent analgesics can produce effects which may obscure the clinical course of patients with head injuries. Therefore, NUBAIN should be used in these circumstances only when essential, and then should be administered with extreme caution. **Interaction With Other Central Nervous System Depressants** Although NUBAIN possesses narcotic antagonist activity, there is evidence that in nondependent patients it will not antagonize a narcotic analgesic administered just before, concurrently, or just after an injection of NUBAIN. Therefore, patients receiving a narcotic analgesic, general anesthetics, phenothiazines, or other tranquilizers, sedatives, hypnotics, or other CNS depressants (including alcohol) concomitantly with NUBAIN may exhibit an additive effect. When such combined therapy is contemplated, the dose of one or both agents should be reduced. **Sulfites Sensitivity** NUBAIN contains sodium metabisulfite, a sulfite that may cause allergic-type reactions (e.g., hives, itching, wheezing, anaphylaxis) in certain susceptible persons. Although the overall prevalence of sulfite sensitivity in the general population is probably low, it is seen more frequently in asthmatics or in atopic nonasthmatic persons.

PRECAUTIONS Impaired Respiration At the usual adult dose of 10 mg/70 kg, NUBAIN causes some respiratory depression approximately equal to that produced by equal doses of morphine. However, in contrast to morphine, respiratory depression is not appreciably increased with higher doses of NUBAIN. Respiratory depression induced by NUBAIN can be reversed by NARCAN® (naloxone hydrochloride) when indicated. NUBAIN should be administered with caution at low doses to patients with impaired respiration (e.g., from other medication, uremia, bronchial asthma, severe infection, cyanosis or respiratory obstructions). **Impaired Renal or Hepatic Function** Because NUBAIN is metabolized in the liver and excreted by the kidneys, patients with renal or liver dysfunction may overreact to customary doses. Therefore, in these individuals, NUBAIN should be used with caution and administered in reduced amounts. **Myocardial Infarction** As with all potent analgesics, NUBAIN should be used with caution in patients with myocardial infarction who have nausea or vomiting. **Biliary Tract Surgery** As with all narcotic analgesics, NUBAIN should be used with caution in patients about to undergo surgery of the biliary tract since it may cause spasm of the sphincter of Oddi.

ADVERSE REACTIONS The most frequent adverse reaction in 1066 patients treated with NUBAIN is sedation 381 (36%). Less frequent reactions are sweaty/clammy 99 (9%); nausea/vomiting 68 (6%); dizziness/vertigo 58 (5%); dry mouth 44 (4%); and headache 27 (3%). Other adverse reactions which may occur (reported incidence of 1% or less) are: **CNS Effects** Nervousness, depression, restlessness, crying, euphoria, floating, hostility, unusual dreams, confusion, faintness, hallucinations, dysphoria, feeling of heaviness, numbness, tingling, unreality. The incidence of psychotomimetic effects, such as unreality, depersonalization, delusions, dysphoria and hallucinations has been shown to be less than that which occurs with pentazocine. **Cardiovascular** Hypertension, hypotension, bradycardia, tachycardia. **Gastrointestinal** Cramps, dyspepsia, bitter taste. **Respiration** Depression, dyspnea, asthma. **Dermatological** Itching, burning, urticaria. **Miscellaneous** Speech difficulty, urinary urgency, blurred vision, flushing and warmth. **Patients Dependent on Narcotics** Patients who have been taking narcotics chronically may experience withdrawal symptoms upon the administration of NUBAIN. If unduly troublesome, narcotic withdrawal symptoms can be controlled by the slow intravenous administration of small increments of morphine, until relief occurs. If the previous analgesic was morphine, meperidine, codeine, or other narcotic with similar duration of activity, one-fourth of the anticipated dose of NUBAIN can be administered initially and the patient observed for signs of withdrawal, i.e., abdominal cramps, nausea and vomiting, lacrimation, rhinorrhea, anxiety, restlessness, elevation of temperature or piloerection. If untoward symptoms do not occur, progressively larger doses may be tried at appropriate intervals until the desired level of analgesia is obtained with NUBAIN. **Management of Overdosage** The immediate intravenous administration of NARCAN® (naloxone hydrochloride) is a specific antidote. Oxygen, intravenous fluids, vasopressors and other supportive measures should be used as indicated. The administration of single doses of 72 mg of NUBAIN subcutaneously to eight normal subjects has been reported to have resulted primarily in symptoms of sleepiness and mild dysphoria.

Presidential Address: The Craft of Surgery, Its Changing Face

CHARLES G. DRAKE, M.D., F.R.C.S.C., F.A.C.S.

From the Division of Neurosurgery, Department of Neurological Services, University Hospital, London, Ontario, Canada

IN HIS ADDRESS to this Association in 1969, Owen Wangensteen remarked that the Presidential Address should be an annual lectureship on the status, outlook, and vistas of surgery.[1] Today I propose to review the status and outlook for surgery, with special reference to what I consider the craft of surgery and with particular attention to my own interest: neurologic surgery.

Momentous events in the last century and a half have shaped the face of surgery, its science and its craft, even though surgery is still basically the use of hands and tools to modify or eliminate malfunction and disease to prolong life and enhance its quality and dignity. Shires described the last half of the 19th century as the third surgical renaissance that laid the foundation for modern surgery, beginning with ether and chloroform anesthesia in 1848, followed by the work of Pasteur and Lister leading to antisepsis and asepsis for surgical wounds.[2] There followed a century of remarkable growth in the technical aspects of surgery, including the advances resulting from experience in two world wars. Every body cavity and viscus were invaded for the eradication of disease or the repair of injury. But the modern zenith of surgery came only after World War II with the introduction of antibiotics and the development of surgical biology—Shires fourth surgical renaissance—wherein surgical technology advanced incredibly on the basis of increasing knowledge of human physiology and chemistry and their maintenance or restoration. But other events, occurring even now, are changing the face of surgery again.

A year ago, a newspaper writer asked what effect would occur in neurosurgery because of the use of endovascular balloon techniques by diagnostic radiologists. He had been told that within a decade neurosurgeons would no longer be operating on intracranial aneurysms, a challenging technical surgical problem to which I and many others had devoted much of our working lives.

I well remember the shudder that went through the neurosurgical world in 1974 when Serbinenko, a Moscow neurosurgeon, published his paper first describing endovascular detachment of occluding balloons in the large arterial feeders to cerebral arteriovenous malfor-

---

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21-23, 1987.

Reprint requests: Dr. Charles G. Drake, Professor of Neurosurgery, Division of Neurosurgery, University Hospital, 339 Windermere Road, London, Ontario, Canada N6A 5A5.

Submitted for publication: April 24, 1987.

mations (AVMs). He also had treated two aneurysms by the technique that he refused to disclose. Soon thereafter a few neuroradiologists developed their own techniques, most notably Debrun et al.[3] in Paris and Kerber[4] in Oregon. As our neuroradiologists, including Debrun who joined our unit in 1978, had been deeply involved with such techniques, including the calibrated leak balloon, I was well aware of the state of the art, its potential, and its problems.

A report about the work of the neuroradiologists seemed, at first, to call for a neurosurgical response to the blanket dismissal of neurosurgical treatment of aneurysms. There was no question that the diagnostic radiologists who had moved into interventional radiology were exerting a profound influence in many of surgery's anatomic fields. It was equally true that their skills and results had been advancing steadily in the decade or so after the introduction of balloon technology. However, the neurosurgical success rate for ruptured aneurysms was well over 90% for patients in reasonable condition. Thus, the journalistic predictions of imminent demise of neurosurgical treatment seemed overdrawn.

A surgeon chooses his surgical discipline for differing reasons. For neurosurgery, it seemed to me that no other tissue handled by surgeons was so delicately eloquent and fragile, or demanded such elegant, precise technical skill and gentleness. Operations had to be based on an intimate knowledge of cerebral structure and function, and for no other tissue was there more to be learned. This challenge to the use of hands and instruments of the day was significant in my choice of a surgical career over 40 years ago. Surgeons take deep personal pleasure in helping patients by operative measures and the intensity of the feeling varies directly with the gravity of the disorder, the risk of the surgical invasion, and the balance between risk and the potential for cure.

For this occasion, I have been stimulated to look back over the changes in the craft of neurosurgery and in other surgical sciences occurring over one surgical lifetime in North America since World War II. Even in a cursory survey of this period, it is obvious that many profound changes in the face of surgery have occurred and are continuing to do so. On the one hand these changes may limit certain surgical actions in the classical sense but may at the same time provide broad horizons for expansion. Except for some matters related to government and the law, most changes have benefited the surgical patient. There can be no surgeon in this audience whose work and thought have not been affected profoundly by these events.

Most advances in medicine and general medical technology have an effect on surgery. Who of us has not indelibly imprinted in his memory the first time, near the end of World War II, when we gained access to a vial of dark yellow penicillin generally used for a patient with an overwhelming staphylococcal infection. Our memory of the first computed tomographic (CT) scan is vivid too, and for neurosurgeons, so is the first look at an aneurysm under the microscope.

We may group the changes under three broad headings: (1) general, (2) pharmacology, (3) technology.

General Changes

The social transformation of medicine by government, industry, and third parties has already begun to have some effect on the details of how surgical operations are performed. Insistences on outpatient surgery, for example, is a clear entry into the judgmental decision of the surgeon and may influence significantly the quality of surgical care. Obsession with cost containment and the threat of civil action for unsatisfactory outcome may drive certain procedures and areas of practice into specialized units or even restrict their performance under any circumstances. This is most visible in obstetrics where specialists are abandoning its practice since there is little prospect for relief from enormous penalties after delivery of impaired children, no matter the reason.

The expansionist strivings of limited licensed practitioners and occasional surgeons, such as partially trained family practitioners, are not likely to have a major impact on surgical craftsmanship. However, in a few institutions, podiatrists have been given privileges for major operations on the foot and ankle joints, even up to the knee. The effect on quality may be left to the imagination.

Both the quality and distribution of surgical care are influenced by manpower factors, which have been concerns of this Association and of both the American and Canadian Colleges of Surgeons. If surgical manpower rises so as to diminish appreciably the operative experience of the average surgeon, we could see a diminution in quality from this factor alone. The Study on Surgical Services for the United States (SOSSUS) reported in 1975 that surgical operative loads were light, measured against a presumed optimal level. In the Rhode Island Study[5] the operative work load for general surgeons dropped from 1970 to 1977, whereas the surgeon-to-population ratio rose 22%.

MacLean's study of his surgical staff suggests that Canadian surgeons, nearly all of whom are certified and who number about one-third less per capita than in the United States (30/100,000 Canada *vs.* 51/100,000 U.S.), were reaching acceptable levels, averaging 2900 California relative value scale units (CRV) per annum, probably a low estimate since a few had large research time allotments.[6] Of interest is that English and Welsh surgeons who number about one sixth per capita of the United States and one fourth of Canadian surgeons, have the potential for very high workloads.[7] Overall, they number 7.7/100,000, but there are only two consultant general surgeons per 100,000 population. However, there is a considerable but varying dilution of these large workloads by senior surgical registrars.

SOSSUS, while recommending that the number of physicians performing operations should be decreased and the number of procedures performed by each surgeon should be increased, suggested four ways by which this might be achieved: developing standards for workloads, limiting operations with a CRV greater than 4.0 to board-certified surgeons, reducing the number of trainees, and enforcing strict guidelines for credentialing of surgeons by hospital boards. With the exception of some scattered reduction in medical student intake and numbers of training programs, there has been no thrust to achieve these goals. Any effect of the restriction on government funding for GME will not be felt for some time. However, in the United States, because of oversupply and the medical-legal situation, increasing difficulty is being encountered in obtaining surgical privileges without board certification.

Various public health measures have diminished the number of opportunities for surgical operation. These include the use of iodinized salt to reduce greatly the incidence of colloid goiter and the introduction of poliomyelitis vaccine, which eliminated that most common cause of orthopedic deformities requiring corrective operations. Heart disease and stroke have been reduced sharply since 1968, concomitant with secular trends in diet, the treatment of hypertension, the decline in cigarette smoking, and the effect of penicillin on rheumatic heart disease. The use of aspirin prophylaxis alone may be expected to cut significantly the occurrence of stroke after transient cerebral ischemic attacks from carotid atheroma.[8] However, this is the age of ageing, and the increasing proportion of the aged in our population will raise the need for these and other operations more common in the elderly.

Changing surgical concepts have also served to diminish the gravity of operations for cancer of the breast and cancer of the rectum. The Halsted mastectomy and the Miles operation for rectal tumors have been much less commonly performed, and the virtual abolition of routine tonsillectomy as a childhood operation has been traceable both to antibiotics and to changing surgical attitudes.

Randomized, controlled clinical trials are assuming an increasing role in assessment of surgical treatment because historic comparisons are invalid. There may still be debate over the degree of benefit in such complex projects as the coronary bypass studies. However, it is unquestionable that dramatic relief of anginal symptoms occurs and there is clear prolongation of life in left main stem coronary disease or triple vessel disease with impaired ventricular function.

There have been only two randomized clinical trials of carotid endarterectomy, but neither addressed adequately the benefit or lack of benefit of the procedure. Whisnant's careful review of the literature concluded that carotid endarterectomy may be of value provided the procedures are performed with a sufficiently low complication rate.[9] The postoperative mortality/stroke morbidity rate would probably have to be less than 1% to effect a 50% reduction in stroke at 5 years of follow-up. Even the best published surgical results probably have produced only about a 33% reduction in stroke in 5 years. If, as he suggests, the overall combined mortality and stroke morbidity rate is probably between 6 and 10%, then it is possible that the net effect of carotid endarterectomy is unfavorable. In that about 140,000 carotid endarterectomies were done last year in the United States at great expense, it seems, therefore, that further carefully controlled clinical trial is warranted to determine the subgroups most likely to benefit.

Recently, extra- to intracranial bypass using the superficial temporal anastomosis to the middle cerebral artery was not shown to be of benefit over best medical management overall or in any of the many special subgroups examined, regardless of the abundance of the new perfusion.[10] This was true even for severe middle cerebral artery disease and even in the prevention of a subsequent infarction in the same hemisphere. That this attractive operation, a technically demanding microvascular procedure and which can undoubtedly supply the middle cerebral artery circulation,[11] did not hold its promise for stroke prevention was startling to the neurosurgical world. Most major neurosurgical units had developed small microvascular suture laboratories for training and practice in anticipation of an ever expanding field. With a patency rate over 95%, even in vessels under 1 mm in diameter, the operative morbidity rate in humans was reduced to little more than 3–4% in many units. Many surgeons had embraced the procedure as a special interest and a major time commitment. Now few are performed because of medical-legal concerns for adverse outcome, and most third parties have restrictions on reimbursement for the procedure. Why additional blood flow was not important in the face of apparent hemodynamic insufficiency beyond atheromatous stenosis is still not understood, but it may be that thromboembolism rather than reduced flow is the more important reason. Even so, some neurosurgeons have not accepted the results of the study completely, believing that there must be some groups of patients that should benefit, either in the prevention of stroke or in improvement of brain function from increased perfusion of marginally ischemic regions. The burden of proof looms large for the numbers are likely to be small if existent. If the transiently ischemic brain had an incapacitating headache as a part of its syndrome, akin to the heart's angina, then the intracranial bypass procedure might still flourish.

Pharmacology

The story of pharmacology in surgery in the last four decades is truly remarkable. Beginning with penicillin and the abatement of surgery for sepsis, we have witnessed the unforgettable transformation in outlook for the tuberculous patient after the introduction of streptomyocin. There followed the psychotropic drugs that eliminated the mutilating prefrontal lobotomy. Steroid replacement made possible the radical surgery for pituitary and other suprasellar lesions. Immunosuppressive drugs, particularly cyclosporin A, have improved immeasurably the success of transplant surgery. Adjunctive chemotherapy, while still palliative after most tumor surgery, has allowed, in the case of primary bone sarcoma, limb salvage procedures after wide local resection of the tumor with 5–10-year survival rates of at least 30–40%.

Other discoveries in pharmacology, including the radiopharmaceutical I-131 for Graves disease, have eliminated the need for surgical treatment in many disease states. Gone are the days of Pemberton who in one morning performed 19 thyroidectomies.[12] At that time, 3000 thyroidectomies were done annually at the Mayo Clinic; it declined to 1000 per year in the 1960s and now numbers about 300.[13]

Gastrectomy for peptic ulceration, formerly a commonly used method of treatment, is now performed so rarely that in some units there is concern about the number of cases needed to train residents in its technique. This procedure once separated experienced surgeons from the occasional operator, but in a recent survey of Canadian surgeons in smaller communities, gastric operations were last on their lists of the ten procedures most commonly performed.[14] Surgery for hypertension disappeared with sympathetic receptor blockade. Hormonal therapy is reducing the use of hysterectomy for dysfunctional uterine bleeding. Many neuroendocrinologists use bromokryptine for primary control of pituitary prolactinomas, and new drugs show promise for managing successfully the adenomas responsible for Cushing's disease and acromegaly. The classic Spiller-Frazier operation for tic doloreux is no longer performed, replaced by the drug carbamazepine in most instances. In refractory cases, percutaneous needle sensory rhizolysis by electrolysis or glycerol is used especially in the elderly, but posterior fossa microvascular decompression of the sensory root is gaining favor for those who will tolerate this higher-risk procedure. Open cordotomy for cancer pain has been replaced by percutaneous injection techniques. Even this is on the wane because of epidural narcotic infusion.

The decline of stereotactic intracranial surgery was directly related to the introduction of L-dopa for Parkinson's disease. This operative technique still has limited use for certain tremors and for insertion of electrodes for deep ganglionic stimulation in intractable pain syndromes. However, with CT guidance, its use is burgeoning again for tumor biopsy and computer planned isotope insertion. There are glimpses of horizons for stereotactic implant of drug pumps or even neurotransmitter-secreting fetal tissues into deprived brain regions.[15,16] These are the opening vistas for surgical therapy, despite the losses to pharmacologic management.

Technology

In addition to the major influence of social change and pharmacologic advances, we are seeing an unprecedented impact of technology on surgery. This impact shows itself in the monitoring of patient care in and out of the operating room, in diagnostic imaging, and in newer therapies.

Physiologic monitoring of the critical aspects of bodily function is now a daily routine. This practice has had a remarkable influence on the scope and safety of surgery for major injury and illness in both the operating room and the intensive care unit. It is part of the biologic revolution in surgery in the last four decades. Near instant recognition of trouble is available and corrective measures can be applied early and with precision.

Benefits from technology in surgical therapeutics have had a profound influence on every surgical specialty. The dialysis machine extended the field of kidney transplantation. Gibbon's development of a heart-lung machine launched the epoch of modern cardiac surgery. Cardiopulmonary bypass for both open and closed heart surgery is now one of the most common operative procedures in many large hospitals. Electrocardiographic mapping has made precise surgical ablations possible for reversal of certain arrhythmias.

Charnley's introduction of an artificial hip joint changed the face of orthopedic joint surgery. Joint replacement now constitutes a significant portion of orthopedics with at least 100,000 artificial hips implanted annually in the United States. The development of modern prosthetics is impressive; their daily implantation by most surgical specialties has vastly expanded the benefits of reconstructive surgery.

The operating microscope opened a new world for surgeons devoted to the ear, eye, and brain. More recently those specialists involved in reconstructive microvascular surgery have changed dramatically the extent of tissue transplants and limb reimplantations. A vast increase in the scope and precision of surgery has emerged with the greatly magnified vision and superb illumination associated with new microinstruments.

Even suturing has been changed. The use of needle and thread has been the hallmark of the surgeon for centuries and nowhere more so in the last century than for alimentary surgeons in gut anastomosis. Traditional emphasis on the precision with which the sutures were placed was vital to success after a low anterior resection of the rectum as well as for the more accessible anastomoses in the colon, duodenum, and stomach. Now the stapling machine performs this task with greater efficiency and increased speed. Young surgeons do not seem to mind this change and look upon the stapler as a new surgical art form.

However, there is another side to the technology story in the actual or potential displacement of classical surgical procedures to nonsurgical specialties such as radiology, cardiology, and gastroenterology. This is another form of fragmentation, derived chiefly from advances in fiberoptic endoscopy and imaging for guidance of needles, catheters, and endovascular balloons, and new uses of focused high energy. The disciplines most affected are general surgery, neurosurgery, and cardiovascular surgery and, to a lesser degree, urology.

The development of fiberoptics has revolutionized endoscopy for diagnosis and treatment of many lesions of hollow viscera and joints. Sclerosis of bleeding varices *via* esophagoscopy is replacing most portocaval shunts and endoscopic retrograde cholangiopancreatography (ERCP) of the common duct with stone visualization and removal is making occasional most common duct surgery. In the large bowel, endoscopic polypectomy is replacing laparotomy as is coagulation of bleeding sites. Developments in arthroscopy have led to endoscopic joint surgery, most particularly in replacing open surgery for most meniscal lesions of the knee joint and even for cruciate auto- or allografts. Probably because of their rarity, there has been little enthusiasm for ventriculoscopy for lateral and third ventricle brain lesions despite the clear spinal fluid medium, although there has been some resurgence of third ventriculostomy by this route for noncommunicating hydrocephalus.

Interventional or surgical radiology is expanding rapidly. The techniques of surgical radiology developed from a combination of two different facets of diagnostic radiology. First was the ability to image in different planes with great accuracy using ultrasound, CT, and now magnetic resonance imaging (MRI), the latter soon to be in three dimensions. With this precise guidance of needles, trocars, and catheters, its use for biopsy and other manipulative techniques followed. Secondly was the development of the Seldinger arteriographic technique in navigating the major arterial streams with a catheter. To this, the idea of Fogarty et al. of an inflatable balloon-tipped catheter[17] was modified so that the distended balloon could be detached as a stationary embolus[18] and balloons calibrated to leak at their tips after occlusive distension could be used for superselective angiography or injection of a rapidly polymerizing plastic for local embolization.

Combinations and extension of these techniques have led to treatments that are generally less invasive than comparable surgery. There are four general groups of radiologic procedures: biopsy and abscess drainage, biliary and renal catheterization and manipulation, angioplasty, and embolization. A few isolated techniques do not fit easily into categorization: selective infusions, filter placement, and foreign body removal, mostly iatrogenic.

The old surgical adage "pus somewhere, pus nowhere, pus under the diaphram" no longer pertains with modern imaging. The urgent laparotomy for abscess localization and drainage in the abdomen or thorax is unusual and these emergencies are treated primarily percutaneously by radiologists, the cross-sectional imaging of CT and ultrasound ensuring the safety of the method. Similarly, pancreatic pseudocysts are now treated primarily by percutaneous drainage. In selected cases of lumbar disc disease, translumbar needle chymopapain discolysis is still offered as an alternative to the open surgical procedure, even by radiologists.[19]

Both biliary and renal tracts can be catheterized percutaneously as well as endoscopically. By both routes, various adjunctive techniques are available for stenting, stone removal, electrocutting, or dilatation of strictures. Selection of a percutaneous or endoscopic approach can be affected by the site and type of the lesion, clinical condition of the patient, availability of expert personnel, and may be used alone or in combination. But there have been pleas from surgeons to physicians that, in stenting malignant biliary obstruction transhepatically or by duodenal endoscopy, they should not ignore those strictures that may be amenable to surgical cure by exploration.[20]

Further advances in other areas may render some percutaneous therapy obsolete; electrohydrolic "shock wave" lithotripsy will probably replace percutaneous renal stone removal in about 80% of patients.

Investigations with new percutaneous techniques include metal memory wire stenting of aneurysms,[21] pulmonary artery thrombectomy,[22] islet cell infusion transplantation into the portal vein,[23] treatment of gall bladder disease through drainage techniques,[24] lumbar and thoracic discectomy,[25] and transvenous electrical ablations for supraventricular and ventricular arrhythmias.[26] Remarkably, there have been some experimental attempts with transmitting and nontransmitting laser probes to vaporize, endoarterially, stenosing atheromata of major vessels, even in coronary arteries.[27]

Angioplasty and embolization comprise the endovascular therapeutic side of radiology. Angioplasty has quickly become an accepted treatment for stenosis in peripheral and renal arteries, replacing most endarterectomy and bypass procedures, except for lengthy lesions. Dotter and Judkins[28] originally used a Bougie-type catheter in leg arteries through an arteriotomy but the distensible balloon on a double-lumen catheter developed by Gruntzig and Hopff[29] and introduced percutaneously allows wire guidance and even perfusion beyond. Angioplasty for coronary artery stenosis is receiving an ever widening acceptance such that last year more than 100,000 procedures were done in the United States, even multiple stenoses in the same patient.[30] This is up from the 12,000 done in 1982, an explosive growth of this cardiological alternative to bypass surgery. Acceptance of angioplasty in the carotid and intracranial vessels has lagged because of concern about downstream embolic effects from the detritus and the brief interval to infarction if a dissection or thrombosis occurs. However, its use is increasing for atheromatous stenosis in the cervical carotid and vertebral arteries.[31] Intracranially, four severe incapacitating basilar artery stenoses were submitted to angioplasty but there were two deaths from thrombosis or rupture of the artery.[32] Most recent is the emergence of balloon valvuloplasty for dilatation of calcific aortic and mitral stenosis, apparently with very low morbidity.[33] The balloon technique has even been used transvenously to create intrahepatic portosystemic shunts in a nonoperative approach to life-threatening variceal bleeding.[34]

Throughout the story of surgery is the control of arterial bleeding by an open surgical procedure, in the beginning for peripheral trauma but expanding gradually for arterial rupture in the course of injury or disease in all body cavities and viscera in the last century.

To my knowledge, the first planned use of an artificial embolus to control an arterial rupture was that of Brooks of Nashville in 1931, when for a traumatic carotid cavernous fistula he inserted a piece of muscle into the carotid artery in the neck, relying on the high flow to carry it to and maintain it in the fistulous orifice.[35] Later, Luessenhop and Spence introduced another form of blind embolization for AVMs in the brain.[36] Plastic beads of varying sizes were placed into a carotid arteriotomy, again with reliance on the sump effect to carry them to the enlarged feeding arteries and the nidus.

Modern imaging and catheter techniques have expanded the potential of embolization to all arterial systems with greater accuracy and safety. In little more than a decade, emergency celiotomy and thoracotomy for massive gastrointestinal, bronchial, or traumatic retroperitoneal bleeding are on the wane. Transfemoral superselective angiography will often delineate the site of bleeding, and particulate embolization through the same catheter can be used for occlusion of the bleeding vessel. Embolization of extremely vascular tumors can be useful for palliation or as a preoperative measure to ease the surgeon's task.

Arteriovenous fistulae, whether traumatic or congenital, are most common in the central nervous system and had to be treated by Hunterian proximal arterial occlusion or trapping, typically by sacrifice of the internal carotid artery for traumatic carotid cavernous fistula, with its risk of stroke. Detached balloon(s) in or just beyond the fistula in the varix have replaced the surgical techniques while preserving the carotid in the majority of cases.[37] It is now also the preferred method of occlusion of the internal carotid for other reasons, especially for inoperable giant aneurysms on that artery.[38] While avoiding a surgical procedure, it also lessens the dead space from which thromboembolism may arise.

Stirred by Serbinenko's balloon detachments in two intracranial aneurysms in 1974, there is now a gradually increasing use of this method for these aneurysms, especially in Russia,[39] but emerging in Europe, North America, and Japan.[40] There are many problems that seem unlikely to be overcome easily; the various geometries of aneurysms and their origins, their fragility, and the lack of direct control of either the vehicle or the embolic material or aneurysm rupture. However, the technology is at an early stage and is likely to be improved for completeness of the obliteration of the sac and its safety.

Large AVMs, again most common in the brain, remain one of the major neurosurgical challenges for safe complete removal. Kerber's further development of Dotter's calibrated leak balloon allowed not only superselective angiography of these formidable lesions, but the possibility of injecting a rapidly polymerizing plastic into the nidus through the large feeding arteries. This brain arterial navigation with catheters has reached remarkable proportions. Currently, aided by the high flow, even feeders under 2 mm may be cannulated. Unfortunately, this form of embolization is rarely complete and there have been a few serious complications such as rupture of the artery or AVM or cerebral infarction. However, catheter technology is improving and a search for better perfusates has begun.

To add to this is the radiation story, for it was little known until recently that x-radiation had an effect on brain AVMs.[41] Now highly focused forms of radiation using gamma, electrons, or the Bragg peak of protons are being used on AVMs. Called "radio surgery," it is effective for small lesions but there is little discernible effect on large AVMs. However, it is not inconceivable that neurosurgeons will see little of AVMs in the future: the small ones could be irradiated. For the large lesions, interventional and therapeutic radiologists could combine their methods, embolizing them to the extent possible and submitting the remaining smaller nidus to irradiation to complete the obliteration.

Radio surgery alone has also been shown to produce remission in Cushing's disease from pituitary microadenoma in over 85% of cases, and about 50% of acoustic neuromas are reduced in size.[42]

The art and science of surgery have always been in a state of change as we strive to develop the therapy that is best for the surgical patient, even though it may mean a reduction in the opportunity for operative management. This survey of 40 years of change in surgery under the impact of general, pharmacological, and technological influences should not be viewed as a litany of dismay but more as a record of triumph by adapting to these various changes.

No surgeon should be concerned about the loss of a surgical procedure to a drug or to various forms of focused high energy if these alternatives are safer and more effective. However, physicians untrained in the handling of living tissues with instruments have shown a keen interest in involving themselves with endoscopic or percutaneous instrumental therapy for lesions in the body cavities and in the alimentary, biliary, renal, and vascular systems. These new surgical manipulators—I will not call them surgeons—may have emerged because they are the gate-keepers for gastroenterology and vascular disease. The radiologists, already skilled in percutaneous arterial catheter guidance for positive contrast diagnosis, simply injected the embolic material or added balloons to their catheters, a technology that had been developed by surgeons. On the other hand, most general surgeons, vascular surgeons, and neurosurgeons have not pursued these innovations probably because they were misjudged as minor in scope and in technical demands, as well as consuming time better devoted to "cutting" surgery. In addition, there was the barrier to the use of the appropriate x-ray machines that require professional radiological guidance and represent a massive capital investment.

In comment on the surrender of postoperative thoracic surgical care to the intensivist, Magovern continued as an aside: "Indeed, one suspects that if we had kept our focus broader than the operating room, we would not be losing pacemakers to the cardiologist, needle aspiration biopsy to the radiologist and endoscopy to the pulmonologist."[43] In Canada, because of larger surgical workloads and government restrictions on hospital facilities, there is little incentive for surgeons to become involved with these new technologies. However, cardiologists saw the potential and have kept most coronary angioplasty away from the radiologists. Most alimentary surgeons do some of the endoscopic large bowel procedures but only a few have learned ERCP and biliary tract manipulation for stone or stenting, which was developed in the early 1970s and widely used in West Germany and Japan.

A few neurosurgeons are still involved with stereotactic procedures using the new imaging in the brain and for needle placement for ablative procedures directed against trigeminal and body pain. In Japan and at least in Moscow and Kiev, neurosurgeons continue to be in charge of cerebral endovascular procedures, but I know of none in North America or Europe so engaged. The applications from North Americans for training in these techniques in our radiological unit come not from surgeons but from physicians.

Is the disinterest of North American surgeons in involvement with these new interventions using modern imaging and now done by physicians a mistake? I do not deny the physician's knowledge of the physics and hazards of imaging or their manipulative skills in guiding needles and catheters. I am concerned, however, by their lack of training in surgical handling of tissues and the absence of detailed knowledge of surgical disease states and their intimate pathology that is best acquired over long years of training and experience. I suspect most radiologists know aneurysms and AVMs only as shadows on an x-ray film or a television screen and have not seen their infinite variety, complexity, and fragility as exposed at craniotomy or know their morbidity.

It can only be surmised how these new technical developments will evolve, but it is reasonable to predict a burgeoning in experimentation and a diffusion of their use. Whereas now these techniques are used only by a few skilled physicians and radiologists, the potential volume of work is enormous, particularly if coronary and carotid angioplasty can be made safe and effective. If the need materializes, the replication of "invasive" radiologists by preceptorship training may well become exponential so that surgical radiology will be available in at least most large hospitals within a few years. One can foresee too that vascular surgeons and neurosurgeons and their operating rooms would have to remain on standby to deal with the complications, just as cardiac surgeons now do for coronary angioplasty. Further, the production of large numbers of these physician-operators will inevitably lead to problems associated with dilution of judgement and experience.

Three possibilities may be envisioned for the evolution of invasive radiology in North America. The first would be to continue to admit patients on the surgical service and have the surgeon share responsibility with the radiologist as now occurs in most units. In this setting, the radiologist will profit from the accumulated surgical knowledge of the disorder and its patterns, which are invaluable in the decision process, in avoidance of technical pitfalls and in perceptive follow-up.

The second option would be the development of special radiological units with bed allotment and admitting privileges; these would be staffed by radiologists and their residents, as has occurred at Johns Hopkins.[44] Such an arrangement risks development of these techniques in isolation from the mainstream of surgery, relying, as in the case of limited license practitioners, on consultation for general and emergency medical and surgical care. Some radiologists believe this is the most appropriate arrangement for their new specialty. They have stated that "this broadens the referral base because community physicians will refer patients for treatment such as peripheral angioplasty without losing control of the patients to a clinical colleague on whom they must depend to obtain our consultation."[44] Further, there is chronic frustration among many radiologists who believe that self interest by some referring surgeons plays too big a role in selection of an appropriate therapy. This has led, in the radiologists' view, to gross underutilization of some newer procedures.[45] They even suggest "a radiological second opinion" as an option before patients undergo certain elective surgical procedures.[46] Radiologists fancy that this might result in improved or equivalent care at less cost and lower morbidity.

A third possibility is the emergence of a new type of practitioner, one with training in both surgery and radiology at a resident level and certification in one or other specialty. Such practitioners might be acceptable for work in either department. Subspecialty recognition of interventional radiology in the form of "added qualification" is being considered by the American Board of Radiology.[46] Their proposed revision of special requirements states it is expected that each resident will have experience in interventional procedures, angioplasty, embolization and infusion procedures, and percutaneous introduction techniques in the biliary and genitourinary systems.

McLuhan's electric age is upon us; surgeons might well regard it as the age of imaging. I have recently developed the conviction, that before it is too late, some young surgeons should become involved with the new imaging and the developing endoscopic techniques, especially in vascular surgery. At least in the beginning, the development of such young surgeons should be done in partnership with their radiological colleagues because it will be necessary to learn many important skills. In this way, development would be complementary rather than competitive between specialty fields. Few surgeons may have access to machines where the cost of imaging can be duplicated with appropriate technical help in the way some cardiologists have managed.

The same may be said for most other aspects of surgical radiology, at least until it can be seen whether or not surgeons can carry further these new and different surgical adventures. In the past, surgeons have shown no lack of ingenuity in technical matters. There should be no thought that these percutaneous techniques are beneath the dignity of a surgeon. I recall the extended discussion in the councils of ophthalmology and in the Board of Regents of the American College of Surgeons as to whether an ophthalmologist who restricted his practice to laser surgery was truly a surgeon; it was decided in the affirmative. Similarly, ultramicrosurgery, about which some speculate, would surely have to be done with machines.

Surgical horizons are broad; they beckon for all the surgical specialties. However, greater changes in the face of surgery will probably come from pharmacology, immunology, and technology. Advances are usually unanticipated. They often come not from intraspecialty expertise, but from other fields of endeavor. The enquiring investigative surgeon must keep abreast of these developments in fundamental science and new technology and become involved with their application to surgical disease. Young surgeons should not shy away from the often incredible complexity of newer basic developments. Immunology promises to marshal our inner defenses against infection and malignancy. In neuroscience the rapidly advancing story of the neurotransmitters mediating central nervous system effects may result in a new field of "implantation." Mann believes that we can expect to see intense effort being made in research fields related to cardiovascular disease and cancer, which are now by far the killing diseases of the mature and aged.[47] "We must surely expect to see sacrifices made in order to drive our knowledge of these diseases nearer to the point in their molecular biology at which rational therapeutics can evolve meaningful preventatives and remedies. This effort must be expected to preoccupy the next few decades, for we have already reached the point at which our knowledge of the oncogenes is likely, within the next few years, to be applied to the management of cancer." "Most startling of all, and within not much more than a decade, it has become fairly clear that genetic engineering and related technology represents the biggest single advance in the lif sciences since the advent of the antibiotics." What effect these genetically engineered vaccines and monoclona antibodies and other unborn technology will have on th surgical craft is unclear, but effect there will be, if only as with the antibiotics, to extend even further the scope and depth of surgery.

I close with a comment I have made mostly to neurosurgeons, but it applies to all the surgical sciences where so much remains unknown: that academic surgeons should exploit one great advantage they possess over the basic scientist in having exposed daily some organ, lesion, or other structure for study. That must be why Wilder Penfield said "The opportunity to learn walks with any surgeon who enters the operating room with questions on his mind."

Pigment Gallstones Form as a Composite of Bacterial Microcolonies and Pigment Solids

LYGIA STEWART, M.D., ALISON L. SMITH, M.D., CARLOS A. PELLEGRINI, M.D.,
ROGER W. MOTSON, M.D., and LAWRENCE W. WAY, M.D.

Although previous studies have suggested that bacteria may contribute to pigment gallstone formation, the current experiments provide evidence that bacteria have a central role in this process. The studies included scanning electron microscopy (SEM) of gallstones, measurements of bacterial adherence to gallstones *in vitro*, and determination of glycocalyx elaboration by biliary bacteria. Gallstones from 85 patients were studied under SEM. Twenty-five (78%) of 32 pigment stones had evidence of bacterial microcolonies throughout the interior of the stones. Bacteria were absent from the interior of all 35 cholesterol stones studied. Composite stones (stones with separate pigment and cholesterol portions) showed evidence of bacteria within the pigment portions in 14 (78%) of 18 cases. Biliary bacteria adhered to the surface of pigment gallstones *in vitro* in 35 (90%) of 39 cases, compared with three (8%) of 39 cholesterol stones. Glycocalyx was elaborated by bacteria isolated from nine (82%) of 11 patients with either pigment or composite gallstones. One (33%) of three bacterial species from patients with cholesterol gallstone disease produced glycocalyx. These studies indicate that most pigment gallstones obtained from patients in Western cultures form as a composite of bacteria, bacterial glycocalyx, and pigment solids. Bacteria were found in the majority of black as well as brown pigment stones. These findings serve as the basis of a new theory of pigment stone formation in which bacteria and glycocalyx are postulated to be responsible for the precipitation and subsequent agglomeration of bilirubin pigment. These results also suggest that sepsis is more common in pigment gallstone disease because the stones can serve as a sanctuary for bacteria.

From the Surgical Service, Veterans Administration Medical Center, San Francisco, and the Department of Surgery, University of California, San Francisco, San Francisco, California, and Colchester Hospitals, Essex, England

PREVIOUS STUDIES HAVE SUGGESTED that bacteria may have a special role in the pathogenesis and clinical manifestations of pigment gallstone disease. For example, we[1] and others[2-4] have shown that infectious complications are much more common in patients with pigment than with cholesterol gallstone disease. However, the role that bacteria play in the formation of pigment gallstones remains incompletely defined.

Maki postulated that bacteria, by secreting β-glucuronidase, could deconjugate bilirubin diglucuronide, which would then precipitate as calcium bilirubinate.[5-7] He believed that the precipitate was probably cemented together to form macroscopic stones by biliary anionic glycoproteins.

Since Maki's theory was presented in 1966, many experiments have been performed to test its tenets. Currently, the generally accepted view is that pigment gallstones can be divided into two types.[8-11] The first type of pigment gallstone is the brown, earthy stone, which is said to occur principally in the Orient. It consists mainly of calcium bilirubinate and calcium palmitate and is believed to develop as the result of infection and biliary stasis. These brown pigment stones typically originate in the common bile duct in preference to the gallbladder. The second type is the black pigment stone, which usually forms in the gallbladder, contains bilirubin polymers in addition to calcium bilirubinate, and is believed to be unrelated to infection. With few exceptions, patients in Western countries who have pigment gallstones have been considered to belong in this second category.[11] The pathogenesis of black pigment stones involves hemolysis in some cases, but in most cases the cause is unknown. Thus, Maki's theory about the origin of pigment stones has been generally accepted for brown stones found in patients in the Orient, but not for the majority of stones found in patients in Western countries.

Since Maki implicated anionic glycoproteins in pigment stone formation, little work has been done to identify specifically how pigment solids become com-

---

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

pacted into stones.[12] Recently, bacteria have been shown to secrete exopolymers, most often referred to as glycocalyx, which are associated with bacterial microcolony formation on foreign bodies.[13-18] This substance, an anionic glycoprotein, is believed to contribute to the ability of bacteria to adhere to surfaces and to resist the effects of antibiotics, phagocytes, antibodies, and surfactants. Glycocalyx can also serve as an ion exchange resin for nutrients needed by the proliferating bacterial colony.

In the current study we examined some of these ideas and have made new observations on the composition of pigment gallstones. The following experiments were performed: a study of the morphology of gallstones using scanning electron microscopy (SEM); measurements of the affinity of bacteria for the surfaces of pigment and cholesterol gallstones *in vitro;* and a determination of the ability of biliary bacteria to elaborate glycocalyx. The results provide substantial new evidence that implicates bacteria in the formation of most pigment stones encountered in Western cultures.

Methods

Morphology of Gallstones

Two categories of gallstones were studied: fresh stones from 32 patients and previously air-dried stones from 53 patients. Only five patients, all Filipinos, had lived in the Orient for an extended period, but they were not recent immigrants. The stones were classified according to their source (gallbladder or common bile duct), gross visual appearance, and composition (Table 1).

The fresh stones were collected and studied prospectively between October 1985 and April 1987. The 32 patients ranged in age from 19 to 96 years and included 23 men and nine women. The ethnic distribution was 21 white patients, four black patients, five Filipino patients, one Hispanic patient, and one Chinese patient. Detailed clinical data were available for all 32 patients.

The air-dried stones were collected between October 1978 and December 1986. This group included gallstones obtained from 15 patients from Essex, England and 38 patients from San Francisco. Clinical data were available on 39 of these patients. The patients ranged in age from 29 to 81 years and included 19 men and 20 women. The ethnic heritage of these patients was as follows: 31 white, one black, five Filipino, one Chinese, and one Malaysian.

The fresh stones were processed immediately after removal from the patients and were not allowed to desiccate. After being photographed, the stones were rinsed in sterile saline and fixed in 5% gluteraldehyde–0.1 M cacodylate buffer at pH 7.0 for 2–10 days, depending on stone size. They were then buffered in 0.1 M cacodylate buffer for at least 1 hour, dehydrated through ascending ethanol concentrations, and critical-point dried. The air-dried stones did not require the above processing. All stones were split and then gold or platinum sputter-coated to 25–40-nm thickness. The surface and interior of each stone was examined under SEM at 10–20 kV using an ISI DS-130 or Cambridge S-150 scanning electron microscope.

TABLE 1. *Classification of Gallstones (106 Stones from 85 Patients)*

Cholesterol	GB	10	17	27
	CBD	5	12	17
Composite	GB	5	4	9
	CBD	2	9	11

Bacterial Adherence to Gallstones

The tendency for bacteria to adhere to gallstones was studied using 78 gallstones (39 pigment and 39 cholesterol). The gallstones had previously been allowed to dry and were sterilized for the purpose of this experiment using ethanol or gas sterilization. For each experiment, 1–3 pigment and 1–3 cholesterol stones were individually incubated in identical solutions. The stones were incubated in a 37 C water bath for 1–3 days in a bacterial suspension of 10^7–10^8 CFU/mL with tryptic soy broth (36 stones) or human bile (42 stones). Fifteen species of bacteria isolated from bile were studied: *Escherichia coli* (7), Enterococcus (3), *Klebsiella pneumoniae* (3), *Pseudomonas aeruginosa* (1), and mixed gastrointestinal flora (1). The bile used for the incubation was obtained from seven patients. Two of these patients had bile collected from T-tubes after operation, one patient had bile collected at operation, two patients had neoplastic biliary obstructions with sterile bile, and two patients had infected bile (one had gallstone disease and one had a benign biliary stricture). The biles were sterilized by passage through a 0.45-millipore filter and were plated to confirm their sterility.

After incubation, each stone was rinsed in sterile saline and fixed in 5% gluteraldehyde–0.1 M cacodylate buffer at pH 7.0. The specimens were further rinsed with 0.1 M cacodylate buffer for 1 hour, dehydrated through ascending ethanol concentrations, critical-point dried, and gold or platinum sputter-coated to 25–40-nm thickness. The stones were examined under SEM (ISI DS-130 or Cambridge S-150) at 10–20 kV to determine the presence of bacterial microcolonies adherent to the surface.

Glycocalyx and Biliary Bacteria

The ability of bacteria to elaborate glycocalyx was determined using ruthenium red and PAS staining. Thirty-one species of bacteria were obtained from bile

cultures from 14 patients. The species included 11 *E. coli,* four *K. pneumoniae,* two Enterococcus, one *P. aeruginosa,* one *Streptococcus viridans,* one *Proteus mirabilis,* one *Klebsiella oxytoca,* and 10 other gut species that were not specifically identified. Each bacterial isolate was incubated overnight in tryptic soy broth at 37 C. Next, 100-μL aliquots of the bacterial suspensions were placed onto glass slides, air-dried, and gently heat fixed. The slides were stained with ruthenium red as described by Mills et al.[14] or PAS. Glycocalyx elaborated by bacteria was assessed from appropriate background staining under light microscopy.

Culture Data

Results of bile cultures obtained from 29 patients during operation were tabulated and compared with

stone composition, stone source, and SEM findings of the corresponding gallstones.

Results

Morphology of Gallstones

The cholesterol and pigment stones had distinctive appearances both grossly and by SEM. The gross visual estimate of stone composition always conformed with the SEM characteristics of the stone.

Pigment stones. Although the gross appearances of pigment stones from different patients varied, the solid material in these stones looked similar under SEM. The surfaces of pigment gallstones exhibited an amorphous, barren, desert-like landscape. The interior of pigment stones consisted of small (<0.5 μm) granules of varying size and shape studding the field (Figs. 1A and B).

Twelve (92%) of 13 fresh pigment gallstones had bacterial microcolonies on their surface and/or comprising the matrix of the stone (Figs. 2A and B) (Table 2). All stones with bacteria on their surface also had bacteria within their interior. All common duct pigment stones had bacterial microcolonies easily identifiable by SEM (Figs. 3A and B.). The fresh pigment gallstones from only one patient did not demonstrate bacteria (Figs. 4A and B). These were gallbladder stones obtained from a 67-year-old man who had a history of hemolysis due to an aortic valve prosthesis.

TABLE 2. *Relationship of SEM Findings to Type of Gallstone*

Stone	No. of Patients	State	Positive SEM	Comments
Pigment	13	Fresh	12 (92%)	Bacteria and/or casts
Pigment	19	Dried	13 (68%)	Bacteria and/or casts
Cholesterol	12	Fresh	1 (8%)	Bacteria and/or casts
Cholesterol	23	Dried	0	Sterile
Composite	7	Fresh	5 (70%)	Bacteria and/or casts in pigment portion only
Composite	11	Dried	9 (82%)	Bacteria and/or casts in pigment portion only

Both fresh and air-dried pigment stones also exhibited many spaces or troughs in the pigment solid (1–2 μm in diameter and 2–4 μm in length), which occurred in groups (Figs. 5A and B). In the fresh pigment stones, the spaces usually contained bacteria, but bacteria were seen only in dried stones that were studied within 10 months of removal. After 10 months, the cavities were empty. These cavities, which we called "bacterial casts," represent spaces currently or previously occupied by bacteria.

To document that these casts were actually physical impressions of bacteria, fresh stones from two patients were examined serially. The first set (one stone from each patient) was processed and examined immediately, and the second set was processed after being allowed to dry at room temperature for 2 months. Bacteria were present within casts on the first examination in both cases, but 2 months later the casts were entirely empty of bacteria in one patient and only sparsely populated with bacteria in the other (Fig. 6).

Thirteen (68%) of 19 air-dried pigment stones showed bacteria and/or bacterial casts in their interior (Figs. 7A and B). The pigment stones from all eight patients from England, all of whom were white, showed evidence of bacteria. Of the patients whose stones displayed no evidence of bacteria, one had a history of hemolysis due to hereditary spherocytosis. There were no distinguishing features common to the other five patients.

Cholesterol stones. The surfaces and interiors of cholesterol stones showed crystals in oakleaf, needle-like, and slab forms (Figs. 8A and B). The size of these crystals varied, but they always exhibited sharp, squared-off borders and uniformity within a given field.

One (8%) of 12 fresh cholesterol gallstones examined demonstrated bacteria on its surface. This cholesterol stone was obtained from a patient whose bile culture grew Klebsiella, Streptococcus, and Proteus. No bacteria or bacterial casts were present within the interiors of any fresh cholesterol stones. In addition, none of the dried cholesterol stones had evidence of bacteria or bacterial casts.

Composite stones. Composite stones were those that on gross inspection had separate pigment and cholesterol portions. The pigment and cholesterol portions of composite stones could be distinguished under SEM from the characteristic features described above. The composite stones from 18 patients could be separated into four groups: cholesterol stones with a small pigment nucleus (6 patients); a pigment stone with a cholesterol coat (1 patient); cholesterol stones with a pigment coat (4 patients); and onion skin stones with alternating layers of pigment and cholesterol (7 patients).

Bacteria were noted within the pigment centers of two (33%) of six cholesterol stones. Bacteria or bacterial casts were seen within the pigment coats of all four composite stones with cholesterol centers and in the center of the one pigment stone with a cholesterol coat. Bacteria or bacterial casts were evident in the pigment areas of all seven composite onion skin stones. None of the cholesterol portions of the composite stones showed bacteria.

Bacterial Adherence to Gallstones

Of the 78 gallstones that were incubated in various bacterial cultures, microcolonies of bacteria were found adherent to the surfaces of 35 (90%) of the 39 pigment gallstones. This included all the bacterial species studied except *P. aeruginosa*. By contrast, only three (8%) of the 39 cholesterol stones demonstrated sparse microcolonies after incubation with a single species of *E. coli*.

Glycocalyx and Biliary Bacteria

One or more bacterial isolates from 10 (71%) of 14 patients stained positively for glycocalyx: six (80%) of eight bacteria from patients with pigment stones; one (33%) of three bacteria from patients with cholesterol stones; and three (100%) of three bacteria from patients with composite stones. The appearance of the glycocalyx staining could be divided into moderately positive and intensely positive. With one exception, intensely positive glycocalyx stains were seen only with bacterial strains obtained from patients with pigment stones. The patient with cholesterol stones who had intense bacterial staining for glycocalyx was the same patient whose stones had surface bacteria under SEM. Bacterial microcolonies were present within all pigment stones whose corresponding bacterial isolates produced glycocalyx.

Culture Data

Bile cultures grew bacteria in 18 (66%) of 29 patients. Pigment gallstone disease was associated with positive bile cultures in 10 (83%) of 12 cases. All patients with pigment common duct stones had positive cultures. The biles from patients with cholesterol gallstones were infected in four (33%) of 12 cases. Finally, bile associated with composite stones had an 80% incidence of biliary infection.

The stones found by SEM to contain bacteria or bacterial casts in their interior were compared with the results of the bile cultures. All pigment stones recovered from patients with positive bile cultures were found by SEM to contain bacteria, whether the stones were obtained from the gallbladder or the common duct. SEM demonstrated bacterial microcolonies on the surface of the stones from only one of four patients with both cholesterol stones and biliary infection.

The results of bile cultures were available for five patients with composite stones: two were stones with pigment cores and cholesterol shells, and three were stones with cholesterol cores and pigment shells. Bile cultures were positive in four of these cases. SEM demonstrated evidence of bacteria in the pigment portion of each of these five stones, whether the pigment was central or on the surface. Composite stones never demonstrated bacteria in the cholesterol portion of the stone.

Discussion

These experiments show that bacteria are present throughout the interior of most fresh pigment gallstones. No bacteria were seen within cholesterol stones, indicating that the relationship of bacteria to pigment stone disease is specific. The patients from whom the pigment stones were removed were not selected; they represented consecutive cases encountered by the authors over several years. The distribution of pigment and cholesterol stones does not reflect their relative frequency among our patient population, however, because we did not examine stones from all patients with cholesterol gallstone disease. With few exceptions the patients were natives of the country where their surgery was performed (*i.e.*, the United States or England) and only five had lived in the Orient for a prolonged period. Therefore, the stones were representative of the spectrum of pigment gallstone disease that characterizes Western cultures.

Pigment stones allowed to dry for several months often contained no bacteria, but their presence was indelibly recorded by the molds they left behind. Several

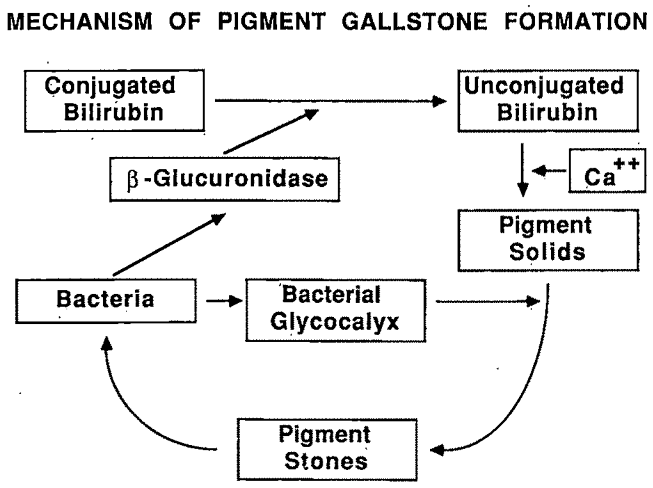

FIG. 9. Proposed mechanism of pigment gallstone formation by bacteria. This theory includes a role for glycocalyx in the development of the stone. Other putative factors discussed in the literature but not directly studied in this experiment have not been included (*e.g.*, inhibitors of β-glucuronidase).

other workers have noted these spaces in pigment stones, but their significance had not been recognized, probably because only dried stones were examined, which contained no bacteria.[10,19–21] We could verify the relationship of bacteria to casts by studying stones serially and noting bacteria when the stones were fresh and their gradual disappearance with time.

The similarity between the SEM appearance of pigment gallstones and that of infectious (struvite) kidney stones is striking.[22,23] These kidney stones also feature bacteria and bacterial casts, and their appearance in some photographs is difficult to distinguish from the pigment gallstones we studied.

A few of our pigment stones had no traces of bacteria. Hemolysis could be implicated as an etiologic factor in two cases, but other etiologic factors were not apparent in the remainder. Therefore, other mechanisms of pigment stone formation remain to be determined. In the composite stones (the stones with distinct pigment and cholesterol portions), bacteria and bacterial casts were present only within the pigment portions of the stones.

The findings of this study call for a revision of current theories concerning the pathogenesis of pigment stones in Western cultures. Although it is accepted that bacteria are involved in the formation of pigment stones in the Orient, this mechanism has been believed to be rare in Western countries.[9,10] The brown "stasis" stones typical of patients in the Orient are said to be uncommon outside that area. When they are encountered, it is believed to be in association with repeated biliary infections and previous biliary surgery. Cetta, for example, demonstrated bacteria by SEM within the stones of two such patients.[3]

We found, however, that bacteria occupied the interior of all kinds of pigment stones, both black and brown. Most of our patients had not had previous biliary surgery and, in general, the clinical severity of their disease was not extraordinary. As suggested by Bernhoft and co-workers,[1] we believe the distinction between black and brown stones has been somewhat overstated in recent literature. Rather than falling neatly into two groups, pigment stones display a spectrum of appearances ranging from the crumbly, milk chocolate, laminated, brown stone at one extreme to the hard, coal black, obsidian-like stone at the other. The pigment stones we studied that contained no bacteria were all of the coal black variety, but those with bacteria spanned the entire spectrum. We have shown also that earthy brown stones are more common in Western countries than has been previously stated, as we found nearly equal numbers of black and brown stones in this and our previous study.[1] Although chemical differences have been detected between black and brown stones,[10] both kinds of stones contain bacteria. Therefore, the differences cannot be explained in terms of bacterial activity.

The *in vitro* experiment demonstrated that biliary bacteria have a special affinity for pigment but not cholesterol solids. Bacterial adherence is usually required before the expression of virulence, and adhesion to a surface has been noted to be the initial step in many bacterial diseases.[24–28] For example, the various *E. coli* sp. responsible for urinary tract infections and gastrointestinal diseases possess adhesins that allow them to adhere specifically to their respective epithelia. Our data suggest a specific adhesin-receptor model by which bacteria attach to pigment solids. Adhesion may be mediated by bacterial glycocalyx, a charged glycoprotein that extends from the bacterial surface and contributes to the ability of bacteria to adhere to other surfaces.[13] The majority of bacteria we isolated from patients with pigment gallstones produced glycocalyx.

There are several ancillary findings of note. One concerns the presence of bacteria within the small pigment center of two cholesterol gallstones. In the past, there was speculation that these dark centers might represent a pigment nidus of crystallization for cholesterol gallstone formation.[29,30] Malet and co-workers,[31] however, found only traces of pigment solids in this type of gallstone, and as a result of their report, the idea fell into disfavor. Although most dark centers of cholesterol stones that we studied by SEM showed cholesterol and no visible pigment, bacteria, or casts, our findings of bacteria and pigment in two stones should revive this possibility.

We have shown that pigment stones form as a composite of bacteria, bacterial glycocalyx, and pigment solids. Maki postulated that bacterial infection can lead to calcium bilirubinate precipitation by the elaboration of the enzyme β-glucuronidase, which deconjugates bilirubin diglucuronide.[5–7] Monoconjugated and unconjugated bilirubin are much less soluble in bile and precipitate as calcium bilirubinate crystals. For macroscopic stone growth, Maki postulated the need for "coagulation factors" that would cement the bilirubinate sediment together. He identified anionic glycoproteins within the matrix of pigment stones by special staining with PAS and Alcian Blue. Similar glycoproteins were also identified in the bile of patients with pigment gallstones.[7] Bacterial glycocalyx is an anionic glycoprotein with the same chemical properties as Maki's coagulation factor. As a polyanionic substance, it also stains with ruthenium red.[14] The elaboration of glycocalyx by bacteria isolated from patients with pigment stones and parallel evidence implicating glycocalyx in the formation of infectious kidney stones[23] suggest that bacterial glycocalyx may be the coagulation factor, but there are other possibilities.[24–28]

Figure 9 illustrates a proposed new theory of pigment gallstone formation. Biliary infection is the initial event. Biliary bacteria produce β-glucuronidase, which deconjugates bilirubin diglucuronide. The bacteria also elaborate glycocalyx, which contributes to the formation of a protected bacterial microcolony on which the pigment coalesces. Glycocalyx, therefore, serves to organize and protect the bacterial microcolony and provide the latticework for pigment deposition. Compared with earlier work, the new elements of this theory are the recognition that: (1) bacteria actually constitute a substantial portion of the stone and are more than just a remote source of β-glucuronidase; (2) bacteria possess specific adhesion properties that are probably instrumental in the creation of the stone; (3) bacteria are responsible for the formation of the majority of black as well as brown stones; and (4) bacteria are primarily responsible for the formation of most of the pigment stones in Western countries as well as in the Orient. In addition to this primary role of bacteria in pigment precipitation and agglomeration, these findings also explain why sepsis is more common in pigment gallstone disease, since the stones serve as a sanctuary that protects the bacteria from endogenous and exogenous antibacterial factors.

Discussion

DR. ROBERT ZEPPA (Miami, Florida): I would like to congratulate the authors on a beautifully illustrated, well-designed, and elegant study.

I rise only for one question. The techniques you mentioned for staining a glycocalyx are nonspecific and stain all glycoproteins. How do you know that that was not gallbladder or bile duct mucus that you stained in the course of these experiments?

DR. FRANK G. MOODY (Houston, Texas): Dr. Stewart has provided us with a rather intriguing concept and started out by saying that she was going to provide us with proof that bacteria, indeed, play a role in the genesis of such stones.

Lygia and I go a long way back to Utah, and we know each other very well, and we also know what proof is. One could, however, interpret the data in a different way. In fact, she has presented evidence that this probably is the case, and that is that pigment has an affinity for bacteria, and as the pigment agglomerates, it tends to trap the bacteria.

I believe this is an important point for the authors to address because if, indeed, bacteria are the nidus, if you will, for the precipitation of the crystals and their agglomeration, then we should be paying more attention to trying to completely rid the biliary tree of infection.

There is no question that the authors are onto something because we all know if we do not provide for the flow of bile that bacteria indeed do accumulate.

I also am curious as to whether the population that they dealt with in San Francisco (probably not in England, but possibly there also) might not have been from the Orient because it is clear that in the Orient, bacteria seem to play a critical role in the formations of stones.

I would like to bring to the attention of the membership two trials of extracorporeal lithotripsy for stones that will be performed in this country in the next 1.5 years. Those of you, like I, who work with patients with gallstones should watch these trials carefully because it is clear from the studies in Munich that gallstones within the gallbladder as well as in the common duct are going to yield to this type of therapy.

Therefore, I ask Dr. Stewart, or whoever closes, how, indeed, are we going to prevent the reformation of these stones once we remove them with lithotripsy or other nonsurgical methods?

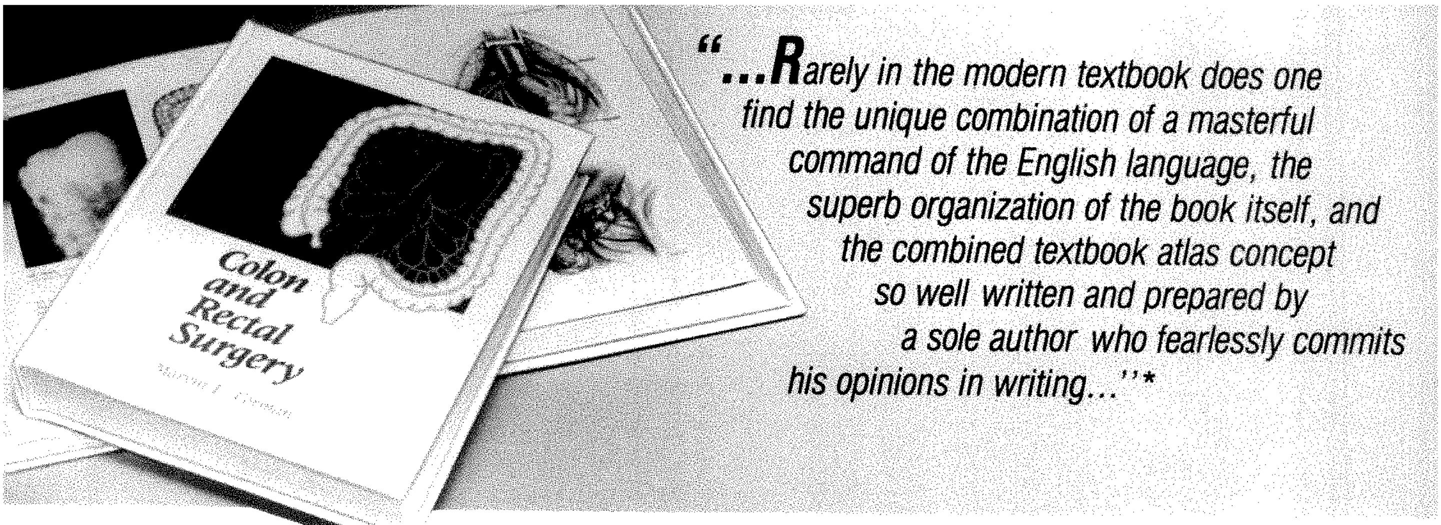
DR. LAWRENCE W. WAY (Closing discussion): I want to thank the discussants for their comments.

In response to Dr. Zeppa's question, staining for glycocalyx was performed on the bacterial isolates, not on the stones. We were interested in knowing whether the bacteria isolated from patients with pigment stones manufactured glycocalyx.

I am not sure that we convinced Dr. Moody. I suppose it is possible that the stones came first and the bacteria second, but that seems unlikely. We were intrigued, for example, by the similarities between the pigment gallstones obtained from our patients and infectious bladder stones. (Slide) This slide illustrates how closely experimentally produced kidney stones (the slide was photographed from an illustration in a report by Takeuchi et al. J Urol 1984; 132:67) resemble gallstones from the common bile duct when examined by scanning electron microscopy. The conditions of the experiment indicate that the urinary stones are primarily the result of bacterial action.

Dr. Moody raised the possibility that we may have unwittingly been studying patients who had Oriental cholangiohepatitis, while intending to focus on stone formation in Western cultures. Only 14 of our patients were of Asian ancestry, and 15 of the white patients lived in England. All of the pigment stones from the English patients showed evidence of bacteria within them. Therefore, we are confident that our conclusions pertain to pigment stone formation in the West.

Lastly, it was asked if this is an infectious process, can it be treated or prevented? There are theoretical possibilities, but nothing that we can think of which would be applicable at the moment. One practical point, however, is that drainage procedures (*e.g.*, choledochoduodenostomy) might be used more liberally in patients with pigment stones.



*"...Rarely in the modern textbook does one find the unique combination of a masterful command of the English language, the superb organization of the book itself, and the combined textbook atlas concept so well written and prepared by a sole author who fearlessly commits his opinions in writing..."**

Colon and Rectal Surgery

By Marvin L. Corman, M.D.

Winner of the 1985 American Medical Writers Association Medical Book Award in the Physician's Category

*"...extremely well-written, readable, and highly informative of the state-of-the-art of colon and rectal surgery...exceptional..."—*Diseases of the Colon and Rectum*

Helps you manage all aspects of diseases and surgery of the anus, rectum and colon

COLON AND RECTAL SURGERY is a comprehensive and abundantly illustrated text/atlas providing an organized approach to the diagnosis and treatment of the more common conditions affecting the anus, rectum and colon. Many esoteric and unusual problems are also discussed; and each chapter contains an extensive bibliography directing you to further study.

"... uniform excellent quality throughout... The extensive illustrations, some of which are in color, are extremely helpful. The bibliography is unusually complete and contains many references to recent articles. The author is to be congratulated for the wealth of material that he has been able to encompass in this one volume..."—The New England Journal of Medicine

Unique single authorship ... insightful commentaries

The single authorship, unique in so comprehensive a text, allows Dr. Corman to emphasize procedures for which he has considerable clinical experience, and to offer insightful commentaries placing concepts into their proper perspective.

"... it is refreshing to be exposed to the perspective of a mature and experienced colon and rectal surgeon who has added the personal touch to a surgical text in good taste, regardless of whether the reader agrees with the conclusion..."
—Diseases of the Colon and Rectum

A superior atlas of surgical techniques

Every chapter is packed with superb illustrations of surgical techniques, showing exactly what you need to know about the full range of colon and rectal conditions. 16 full-color illustrations show the appearance of various conditions such as ulcerative colitis, melanosis coli, pruritus ani, and extramammary Paget's disease. Sharp x-rays, photomicrographs, and tables amplify the text.

"... more completely enhanced with photographs, drawings, and roentgenograms than any other textbook on the market..."
—Mayo Clinic Proceedings

Other important features

- emphasizes reconstructive anorectal surgery—for which Dr. Corman is well known
- fully covers management of cancer and inflammatory bowel disease
- describes in clear and precise detail complex anorectal and colon operations
- contains in-depth discussions of incontinence, ostomy complications and their management, and dermatologic anal problems.

Large 8" x 10" Format. 784 Pages. 818 Illustrations, 16 in Full Color. 49 Tables. 1984. $95.00.

CASE # 24 **AGE:** 55 **SEX:** FEMALE

DIAGNOSIS: CECAL CARCINOMA

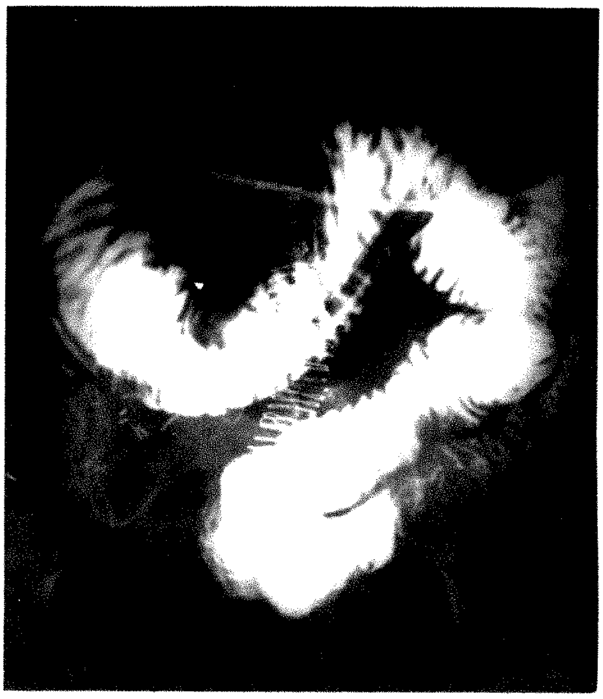
SYMPTOMS: ANEMIA (Hg 6 gm/dl)

OPERATION: RIGHT HEMICOLECTOMY & GASTROSTOMY

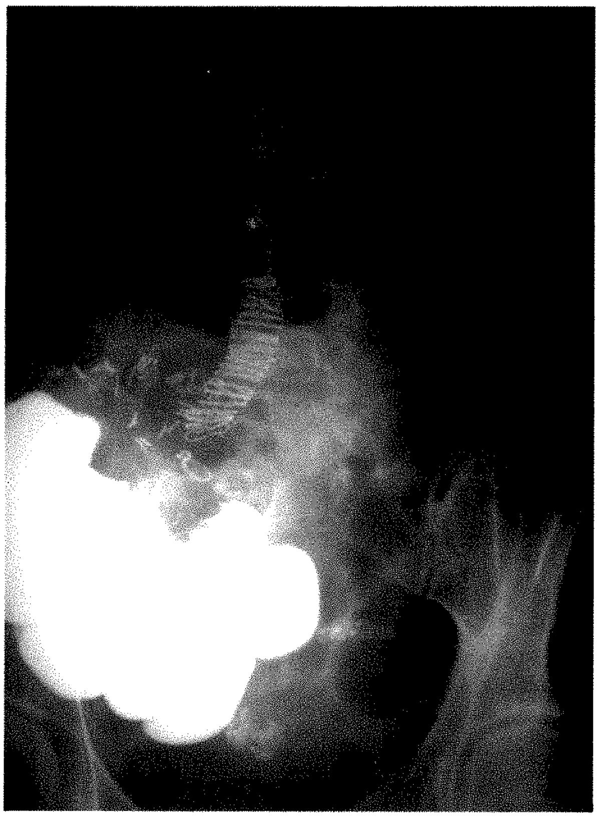
The patient had a right hemicolectomy with stapled (U.S. Surgical Corp) anastomosis and fascia closure and a MOSS® gastrostomy tube. The stomach and proximal duodenum were aspirated, with immediate simultaneous feeding into the distal duodenum.

Barium feeding 5 hours postop documented adequate motility. The deliberate excess was totally removed. No contrast (i.e.: excess feeding) escaped efficient aspiration within the proximal duodenum, to reflux into the stomach. (Figure A) Serial motility study showed barium had traversed the anastomosis and colon, and already was exiting in a spontaneous bowel movement by 21 hours postop. (Figure C)

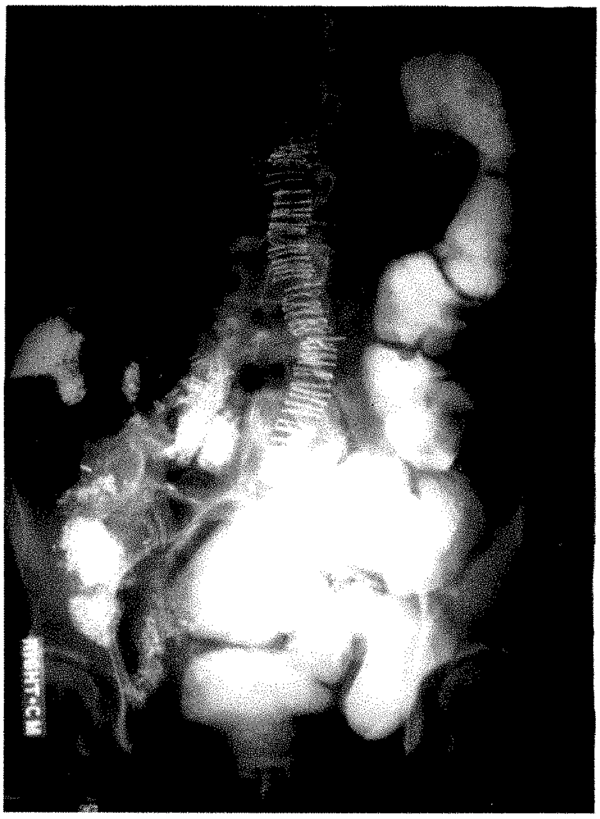
She received 300 ml/hr of Vivonex TEN (Norwich Eaton Pharm), absorbed 5,000 kcal the initial 20 hours, and then tolerated a general diet. She was the 4th patient discharged uneventfully 24 hours after bowel resection and reanastomosis.



A. Study @ 5 minutes (5 hours postop).
Note efficient removal of all excess barium, with none reaching the stomach.



B. Motility @ 4 hours (9 hours postop).
All barium is within the ileum.



C. Motility @ 16 hours (21 hours postop).
Barium is exiting in a spontaneous bowel movement.

Th only parent ral

q12h dosage means cost-effectiveness

- ☐ Cost per day less than Tagamet* Injection q6h**
- ☐ May result in fewer I.V. set-up charges, less nursing time, less pharmacy time, lower administrative costs

Efficacy

Prompt, persistent, predictable pH control for many patients

Tolerability

Excellent tolerability profile—even in critical care patients

Dosing intervals may need to be prolonged or dosage reduced in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine. PEPCID® I.V. (Famotidine, MSD) is contraindicated in patients who are hypersensitive to any component of this medication. The adverse reactions reported for PEPCID Tablets may also occur with PEPCID I.V. In addition, transient irritation at the injection site has been observed with PEPCID I.V.

H_2 antagonist with q 12 h dosage

Indicated in some hospitalized patients with pathological hypersecretory conditions or intractable ulcers or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.

The recommended dosage is 20 mg q 12 h

INJECTION, 10 mg/mL

q12h **Pepcid® IV**

(Famotidine|MSD)

For a Brief Summary of Prescribing Information, please see the following page.

TABLETS
Pepcid®
(Famotidine/MSD)
20 mg and 40 mg

ORAL SUSPENSION
Pepcid®
(Famotidine for Oral Suspension/MSD)
40 mg per 5 mL

INJECTION
Pepcid® IV
(Famotidine/MSD)
10 mg per mL

Contraindications: Hypersensitivity to any component.

Precautions: ***General:*** Symptomatic response to therapy does not preclude the presence of gastric malignancy.

Patients with Severe Renal Insufficiency: Longer intervals between doses or lower doses may be needed in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine (see Clinical Pharmacology and Dosage and Administration sections of Prescribing Information).

Information for Patients: The oral suspension should be shaken vigorously for 5-10 seconds prior to each use, and unused constituted oral suspension should be discarded after 30 days.

Drug Interactions: No drug interactions have been identified. Compounds tested in man include warfarin, theophylline, phenytoin, diazepam, aminopyrine, and antipyrine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In rats and mice given oral doses up to approximately 2500 times the recommended human dose for active duodenal ulcer, there was no evidence of carcinogenic potential, no evidence of a mutagenic effect, and fertility and reproductive performance were not affected.

Pregnancy: *Pregnancy Category B*—There are no adequate or well-controlled studies in pregnant women. Use during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether famotidine is secreted into human milk; however, it is secreted into the milk of lactating rats. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: No dosage adjustment is required based on age but may be necessary in severe renal impairment (see Clinical Pharmacology section of Prescribing Information).

Adverse Reactions: The adverse reactions listed below have been reported during domestic and international clinical trials in approximately 2500 patients. In the placebo-controlled clinical trials, the incidence of adverse experiences with PEPCID Tablets, 40 mg at bedtime, was similar to that with placebo.

Incidence Greater than 1%: The following adverse reactions have been reported to occur in more than 1% of patients on therapy with PEPCID in controlled clinical trials and may be causally related to the drug: headache (4.7%), dizziness (1.3%), constipation (1.2%), and diarrhea (1.7%).

Causal Relationship Unknown: The following other adverse reactions have been reported in clinical trials. While a causal relationship could not be established for these infrequently reported events, causality cannot be excluded. *Body as a Whole*—Fever, asthenia, fatigue. *Cardiovascular*—Palpitations. *Gastrointestinal*—Nausea, vomiting, abdominal discomfort, anorexia, dry mouth, liver enzyme abnormalities. *Hematologic*—Thrombocytopenia. *Hypersensitivity*—Orbital edema, conjunctival injection. *Musculoskeletal*—Musculoskeletal pain, arthralgia. *Nervous System/Psychiatric*—Paresthesias; grand mal seizures (single report); psychic disturbances including depression, anxiety, decreased libido, hallucinations (single report); insomnia; somnolence. *Respiratory*—Bronchospasm. *Skin*—Alopecia, acne, pruritus, rash, dry skin, flushing. *Special Senses*—Tinnitus, taste disorder.

The adverse reactions reported for PEPCID Tablets may also occur with PEPCID Oral Suspension or PEPCID I.V.; in addition, transient irritation at the injection site has been observed with PEPCID I.V.

Management of Overdosage: There is no experience to date with deliberate overdosage. Up to 640 mg/day have been given to patients with pathological hypersecretory conditions with no serious adverse effects. In the event of overdosage, treatment should be symptomatic and supportive. Unabsorbed material should be removed from the gastrointestinal tract, the patient should be monitored, and supportive therapy should be employed.

Dosage and Administration: ***Duodenal Ulcer:*** The recommended adult oral dosage for active duodenal ulcer is 40 mg h.s.; most patients heal within 4 weeks, and it is rarely necessary to use the full dosage for longer than 6 to 8 weeks. A regimen of 20 mg b.i.d. is also effective. For maintenance therapy, the recommended oral dosage is 20 mg h.s.

Pathological Hypersecretory Conditions (e.g., Zollinger-Ellison Syndrome, Multiple Endocrine Adenomas): The dosage varies with the individual patient; the recommended adult oral starting dosage is 20 mg q6h, but some patients may require a higher starting dosage. Dosages should be adjusted to individual patient needs and continued as long as clinically indicated; up to 160 mg q6h have been administered to some patients with severe Zollinger-Ellison syndrome.

Oral Suspension: The Oral Suspension may be substituted for Tablets for those patients who cannot swallow tablets.

Directions for Preparing PEPCID Oral Suspension: Prepare suspension at time of dispensing. Slowly add 46 mL Purified Water. Shake vigorously for 5-10 seconds immediately after adding the water and immediately before use.

Stability of PEPCID Oral Suspension: Unused constituted oral suspension should be discarded after 30 days.

Intravenous Administration: In some hospitalized patients with pathological hypersecretory conditions or intractable ulcers, or in patients who are unable to take oral medication, the recommended intravenous dosage is 20 mg q12h. For preparation of solutions for injection or infusion and for compatible diluents, please see Prescribing Information. Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Concomitant Use of Antacids: Antacids may be given concomitantly if needed.

Dosage Adjustment for Patients with Severe Renal Insufficiency: In patients with severe renal insufficiency (creatinine clearance less than 10 mL/min), the elimination half-life of famotidine may exceed 20 hours, reaching approximately 24 hours in anuric patients. Although no relationship of adverse effects to high plasma levels has been established, to avoid excess accumulation of the drug, the dosage may be reduced to 20 mg h.s. or the dosing interval may be prolonged to 36 to 48 hours as indicated by the patient's clinical response.

How Supplied: Tablets, containing 20 mg or 40 mg famotidine, with hydroxypropyl cellulose, hydroxypropyl methylcellulose, iron oxides, magnesium stearate, microcrystalline cellulose, starch, talc, and titanium dioxide as inactive ingredients, in bottles of 30 and unit-dose packages of 100; Oral Suspension, containing per 5 mL after constitution with 46 mL Purified Water, 40 mg famotidine, with citric acid, flavors, microcrystalline cellulose and carboxymethylcellulose sodium, sucrose, and xanthan gum as inactive ingredients, and sodium benzoate 0.1%, sodium methylparaben 0.1%, and sodium propylparaben 0.02% added as preservatives, in bottles of 400 mg famotidine for constitution; Solution for intravenous injection, containing 10 mg famotidine per mL, with L-aspartic acid 4 mg, mannitol 20 mg, and water for injection q.s. 1 mL as inactive ingredients, and benzyl alcohol 0.9% added as preservative to the multidose vial, as 10x2-mL single-dose vials and as 4-mL vials.

Compazine®

Injection 5 mg./ml.

brand of

prochlorperazine

Available in 25 mg. suppositories, too.

Do not use 'Compazine' in pediatric surgery.

©SmithKline Beckman Corporation, 1985

See brief summary of prescribing information on adjacent page.

The antiemetic physicians prescribe most*

COMPAZINE®

brand of

prochlorperazine

See complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: For control of severe nausea and vomiting.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; pediatric surgery; use in children under 2 years of age or under 20 lbs.; use in children for conditions for which dosage has not been established.

Warnings: The extrapyramidal symptoms which can occur secondary to 'Compazine' may be confused with the central nervous system signs of an undiagnosed primary disease responsible for the vomiting, e.g., Reye's syndrome or other encephalopathy. The use of 'Compazine' and other potential hepatotoxins should be avoided in children and adolescents whose signs and symptoms suggest Reye's syndrome.

May cause tardive dyskinesia in some patients on neuroleptic (antipsychotic) therapy, usually long-term. This syndrome consists of potentially irreversible, involuntary dyskinetic movements. The risk of tardive dyskinesia and likelihood of irreversibility are thought related to duration of treatment and total cumulative dose of neuroleptic drugs.

Use in patients with bone marrow depression only when potential benefits outweigh risks. Patients who develop a hypersensitivity reaction (e.g., blood dyscrasias or jaundice) to a phenothiazine generally should not be reexposed to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Prochlorperazine may intensify or prolong the action of other C.N.S. depressants.

Use in pregnancy is not recommended except in cases so serious and intractable that, in the physician's judgment, drug intervention is required and potential benefits outweigh possible hazards. There have been instances of prolonged jaundice, extrapyramidal signs, hyperreflexia or hyporeflexia in newborn infants whose mothers received phenothiazines. There is evidence that phenothiazines are excreted in the breast milk of nursing mothers.

Precautions: The antiemetic action of 'Compazine' may mask the signs and symptoms of overdosage of other drugs and may obscure the diagnosis and treatment of other conditions such as intestinal obstruction, brain tumor and Reye's syndrome (See Warnings). Postoperative aspiration of vomitus has occurred in a few surgical patients who received prochlorperazine as an antiemetic. When used concomitantly with cancer chemotherapeutic drugs, may obscure vomiting as a sign of these agents' toxicity. Deep sleep and coma have been reported with prochlorperazine, usually with overdosage.

Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent *in vitro*, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis.

Permanently stop neuroleptic therapy if neuromuscular reactions occur in pregnant women or in children.

In children with acute illnesses or dehydration, use only under close supervision. Avoid high doses and parenteral administration when cardiovascular system is impaired since hypotension has occurred. Use cautiously in patients with glaucoma. Use with caution in persons who will be exposed to extreme heat since phenothiazines may interfere with thermoregulatory mechanisms. Phenothiazines can diminish the effect of oral anticoagulants. Phenothiazines can produce alpha-adrenergic blockade. Thiazide diuretics may accentuate orthostatic hypotension that may occur with phenothiazines. Antihypertensive effects of guanethidine and related compounds may be counteracted when phenothiazines are used concomitantly. Concomitant administration of phenothiazines with propranolol results in increased plasma levels of both drugs and may also precipitate phenytoin toxicity. Phenothiazines may lower the convulsive threshold; dosage adjustments of anticonvulsants may be necessary. Presence of phenothiazines may produce false positive phenylketonuria (PKU) test results. Patients should not receive 'Compazine' 48 hours before or 24 hours after myelography with the contrast medium metrizamide.

Adverse Reactions: Drowsiness, dizziness, amenorrhea, blurred vision, skin reactions. Hypotension. Cholestatic jaundice, leukopenia, agranulocytosis. Fatty changes in the liver have been observed in a few patients who died while receiving the drug (no causal relationship has been established). Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, tardive dyskinesia, and a variant, tardive dystonia. Contact dermatitis is a possibility if 'Compazine' Injection (solution) inadvertently gets on hands or clothing.

Other adverse reactions reported with 'Compazine' or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., severe hypotension in mitral insufficiency or pheochromocytoma). Grand mal and petit mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat and organophosphorus insecticides; dryness of mouth, nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, ejaculatory disorders/impotence, priapism, atonic colon, urinary retention, miosis and mydriasis; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; pancytopenia, thrombocytopenic purpura, eosinophilia, hemolytic anemia, aplastic anemia; biliary stasis; hyperglycemia, hypoglycemia, glycosuria, lactation, galactorrhea, gynecomastia, menstrual irregularities, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria,,eczema up to exfoliative dermatitis; asthma, laryngeal edema; angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; mild fever after large I.M. doses; increased appetite; increased weight; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; neuroleptic malignant syndrome, which may be fatal; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits.

EKG changes have been reported. Discontinue long-term, high-dose therapy gradually.

Note: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported.

Supplied: Tablets—5, 10 and 25 mg., in bottles of 100; Spansule® capsules—10, 15 and 30 mg., in bottles of 50; Injection—5 mg./ml. in 2 ml. ampuls, 10 ml. vials and 2 ml. disposable syringes; Suppositories—2½, 5 and 25 mg.; Syrup—5 mg./5 ml.; Single Unit Packages of 100 (intended for institutional use only)—5 and 10 mg. tablets; 10, 15 and 30 mg. 'Spansule' capsules.

WE HA E ONL GOOD THINGS TO S Y ABO T CANC OF TH COLO .

If detected early, the cure rate for colorectal cancer is very high. It can be as high as 75%.

Because we now know how to detect it early. And we know how to fight it once we detect it.

There are three simple checkup guidelines for men and women without symptoms.

One, get a digital exam every year. This is recommended for everyone over 40.

Two, get a stool blood test every year if you are over 50.

Three, after two initial negative tests one year apart, get a procto exam every three to five years if you are over 50.

These guidelines are the best protection against colorectal cancer you can have.

If you're not over 50, please give this information to friends and loved ones who are.

In any case, please help spread the word.

Good news doesn't always travel fast.

AMERICAN CANCER SOCIETY®

Get a checkup. Life is worth it.

Results with the Mustard Operation in Simple Transposition of the Great Arteries

1963–1985

GEORGE A. TRUSLER, M.D., WILLIAM G. WILLIAMS, M.D., KIM F. DUNCAN, M.D., PETER S. HESSLEIN, M.D., LEE N. BENSON, M.D., ROBERT M. FREEDOM, M.D., TERUO IZUKAWA, M.D., and PETER M. OLLEY, M.D.

From May 1963 to December 1985, 329 infants and children underwent repair of simple transposition of the great arteries (TGA) using Mustard's technique. To assess improvement, the patients were separated into two groups by date of operation: Group I, May 1963 to December 1973 (N = 106), and Group II, January 1974 to December 1985 (N = 223). The operative mortality was 11 (10.4%) in Group I and two (0.9%) in Group II. The 10-year actuarial survival rate was 73.4% in Group I and 93.7% in Group II. Baffle complications, similar in both groups, were identified in 81 patients; 19 were major, causing death or requiring reoperation. By latest electrocardiogram, 21 of 45 (46.7%) of Group I patients and 129 of 180 (71.7%) of Group II patients were in normal sinus rhythm. Late ambulatory electrocardiography, however, revealed that a majority of patients had sinus node dysfunction or other dysrhythmias. Right ventricular (RV) angiography revealed definite diminution of RV contractility in 14 (11%) of 126 children. At late follow-up, 113 of 148 (76%) children were in New York Heart Association (NYHA) Class I and 35 of 148 (24%) were in NYHA Class II. Thirty-five (21%) patients were on cardiac medication chiefly for dysrhythmia management. There has been significant improvement in the early and late mortality with the Mustard operation, and serious baffle complications are infrequent. Dysrhythmias continue to be a major problem but the surviving patients are clinically well and relatively few have significant RV dysfunction.

From the Divisions of Cardiovascular Surgery and Cardiology, The Hospital for Sick Children, and the Departments of Surgery and Pediatrics, The University of Toronto, Toronto, Ontario, Canada

MUCH HAS CHANGED in the management of complete transposition of the great arteries (TGA) over the last 25 years. After Mustard[1] first performed his atrial repair in May 1963, there was an immediate awakening of interest in the treatment of TGA. Eventually this lead to a re-examination of other operations, and it was soon found that the Senning[2] atrial repair could produce equally satisfactory results.[3] Later, success was attained with arterial repair, although initially with high mortality.[4] As techniques improved and mortality decreased, arterial repair came to be the preferred treatment in children with TGA and associated ventricular septal defect (VSD).[5,6] Recently arterial repair has been applied to simple TGA in neonates and results are sufficiently competitive to warrant a thorough review of the Mustard procedure.[7–9]

Patients and Methods

From May 1963 to December 1985, at the Hospital for Sick Children in Toronto, 329 infants and children underwent repair of simple TGA using Mustard's technique. This includes children with small inconsequential VSDs or a degree of left ventricular outflow tract obstruction not needing treatment. To assess improvement in results with time, the patients were divided into two groups, those who had repair during the first decade from May 1963 to December 1973 (Group I, N = 106) and those who had repair in the subsequent 12 years from January 1974 to December 1985 (Group II, N = 223) (Table 1).

In the early years, 49% of infants received temporary palliation with a Blalock-Hanlon surgical septectomy. This practice has continued with a higher proportion of atrial septectomies in infants seen initially at our institution than those referred secondarily. The elective age for repair has decreased through the years so that now most Mustard procedures are performed between 6 and 12 months of age.

Originally all repairs were done with cardiopulmonary bypass, but starting in 1972, deep hypothermia and

Early deaths	11 (10.4%)	2 (0.9%)
Late deaths	21 (22.1%)	10 (4.5%)

circulatory arrest were used for infants less than 8–10 kg of body weight, which now includes most patients. Since 1976, we have attempted to minimize intraoperative myocardial ischemic damage by giving cold cardioplegia, at first crystalloid and later blood cardioplegia. In addition, the ventricular myocardium has been kept hypothermic with a cold pericardial bath, now replaced by a special cooling jacket.

There have been a few modifications of the original technique. To excise the atrial septum, an incision is first made from the middle of the foramen ovale to the midpoint of the superior vena caval (SVC) orifice. The ridge of tissue medial to the cut is preserved for its potential to allow conduction from the sinoatrial (SA) node to the atrioventricular (AV) node and also to reduce the danger of cutting the artery to the SA node. An earlier study indicated a significant increase in the incidence of sinus rhythm when this ridge of tissue was preserved.[10] All septum lateral (rightward) to the cut is excised. The coronary sinus is cut back and often a small portion of its wall is carefully excised to enlarge the inferior vena caval (IVC) channel. All large raw areas are oversewn to reduce stricture formation and adhesions to the baffle.

Cardiac catheterization was performed after operation in 126 children (Group I, N = 45; Group II, N = 81) with simple TGA to assess baffle problems, as well as tricuspid valve and right ventricular (RV) function.

Cardiac rhythm was assessed primarily by serial electrocardiography, (EKG) but we examined all ambulatory monitor ("Holter") recordings and programmed stimulation electrophysiological studies (EPS) performed on these children. Holter recordings were obtained with a variety of single-channel and dual-channel systems since 1973, with both manual and automated playback systems. Duration of recordings ranged from 6 to 48 hours, but was almost always for a full 24 hours. EPS recordings were all performed since 1981, following standard atrial pacing protocols.[11–13] All studies were obtained with a Honeywell VR 16 recorder (Honeywell, Markham, Canada) and digitalized with an Apple IIe microcomputer using specially designed software (Apple Canada, Toronto, Canada).

For late results in all patients operated on before January 1981, records were reviewed for the last clinical evaluation. Functional assessment was based on symptoms, medications, and school or work history, as well as New York Heart Association (NYHA) grading for patients other than infants. The source of information included chart reviews for follow-up visits, letters from referring physicians, questionnaires to referring cardiologists, and, in 1984, a telephone interview of 128 patients. RV function was assessed at rest and during supine bicycle exercise by gated equilibrium radionuclide angiography in a small group of patients from our institution who had the Mustard procedure, and has been reported previously.[12] Cardiopulmonary function was also measured during upright graded bicycle exercise in a small asymptomatic cohort (N = 17) over 10 years since repair. Actuarial survival curves were calculated using the life table analysis method.

Results

Ten patients in Group I were lost to follow-up (6 after discharge from hospital and one each at 2, 3, 4, and 6 years after operation). Six patients in Group II were lost to follow-up, all at hospital discharge. These patients were included up to the last follow-up date and then excluded but not considered dead statistically.

Early Deaths

Overall mortality (*i.e.,* less than 30 days after operation or before hospital discharge) was 13 of 329 children (4.0%). In Group I, early mortality was 11 (10.4%) of 106 children and in Group II was two (0.9%) of 223 children (Table 2). There have been no early deaths in the 160 patients who had repair since January 1978. In order of frequency, the causes of death were myocardial failure (7), dysrhythmia (2), cerebral injury (2), bleeding (1), and air embolism (1).

Late Deaths

To date there have been 31 late deaths (9.8%) in the 316 operative survivors. In Group I there were 21 (22.1%) late deaths among the 95 early survivors and in Group II there were 10 (4.5%) late deaths in the 221 early survivors (Table 3). Causes of late death include dysrhythmia (9), sudden death (4), pulmonary venous obstruction (8), cardiac failure (5), and other unusual causes that include baffle detachment (1), pulmonary vascular disease (1), pulmonary vein thrombosis (1), congenital respiratory problems (1), and progressive aortic incompetence (1). Three of four children who died suddenly had shown previous rhythm disturbances: two tachyarrhythmias and one intermittent sinus and junctional rhythm. The fourth child was in sinus rhythm shortly after leaving the hospital and no further record was available. Although most late deaths (*i.e.*, 25) occurred within 4 years of operation, there has been a slow attrition with time, late deaths occurring in postoperative years 6, 10, 11, 12, 15, and 18, respectively (all in Group I). These six deaths were due to dysrhythmia (3), sudden death (1), cardiac failure (1), and pulmonary venous obstruction (1).

Actuarial analysis of the 329 children (Fig. 1) shows an 85.8% 10-year survival rate and an 81.5% 15-year survival rate. When the two groups are compared (Fig. 2), Group II patients have a 5- and 10-year survival rate of 93.7% and 93.7%, respectively, compared with the respective rates of 75.4% and 73.4% in Group I patients. Most of the difference is the greatly reduced operative mortality rate from 10.4% to 0.9% ($p < 0.001$), but there is also a difference in the late mortality rate from 22.1% to 4.5% between 1 month and 4 years ($p = 0.025$).

Postoperative Cardiac Catheterization Data

Baffle Complications

Baffle leaks, although relatively common, are usually small and inconsequential, remaining unidentified until discovered by cardiac catheterization or echocardiography. There were 316 early survivors after Mustard repair of simple TGA; 126 (45 in Group I, 81 in Group II) had at least one postoperative cardiac catheterization (Table 4). In 40 survivors (12.7% but 31.7% of those catheterized), a baffle shunt was found (22 in Group I, 18 in Group II). Most were small but in five survivors the shunt was large. One child died and two children required reoperation.

Of the 316 early survivors, 26 (8.2%) were found to have some narrowing of the SVC channel. Seven were Group I patients and 19 were Group II patients. In 15 of the 26 children, this was mild; it is likely that more follow-up catheterization studies would uncover mild SVC stenosis in other asymptomatic patients. More severe degrees of stenosis were encountered in 11 patients, four with gradients of 5–8 mmHg across the stenosis and six with gradients over 8 mmHg. One child had complete obstruction but was asymptomatic due to run-off

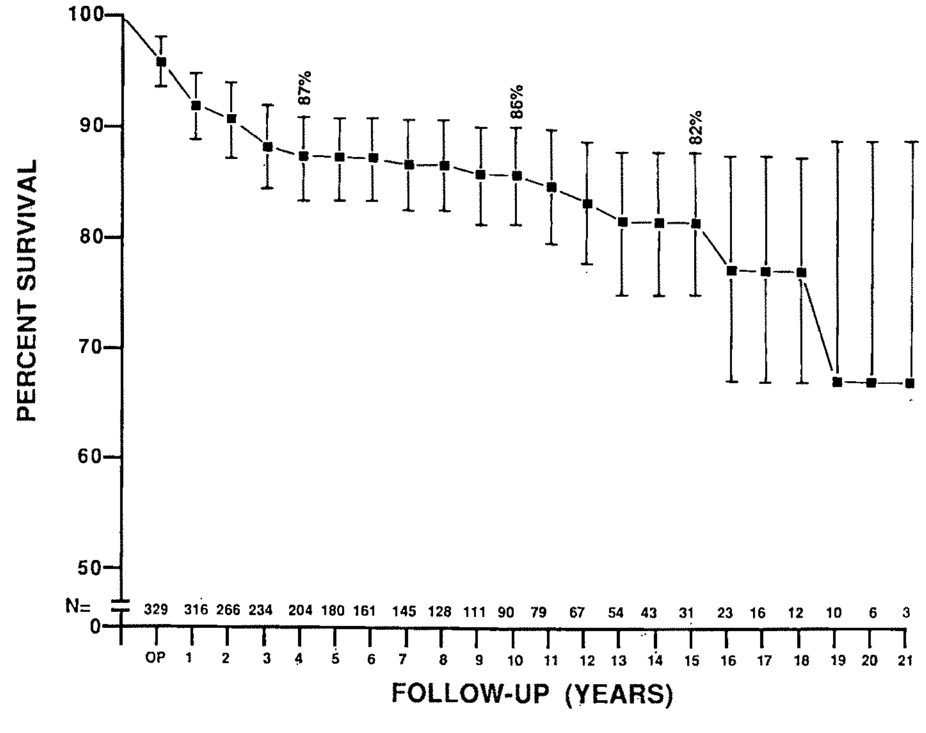

FIG. 1. Actuarial analysis of survival after the Mustard operation in simple TGA for 329 children between 1963 and 1985. The survival rate is 85.8% at 10 years and 81.5% at 15 years.

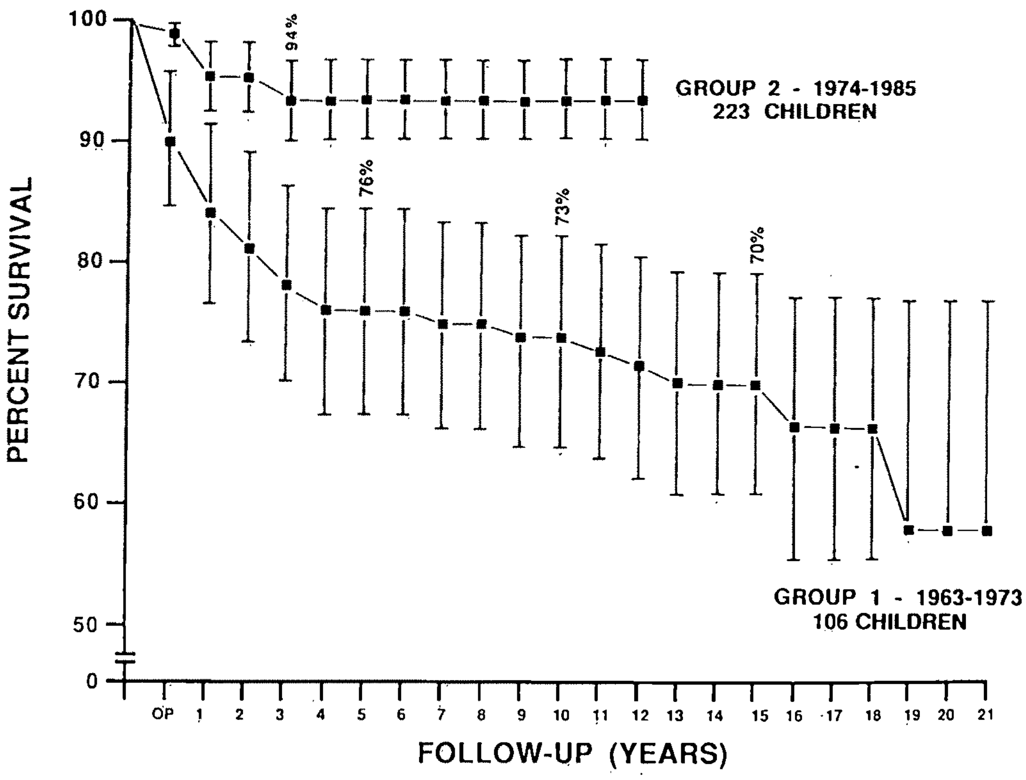

FIG. 2. Graph comparing survival in Group I and Group II patients. Group II patients had a 5- and 10-year survival rate of 93.7% compared with 75.4% and 73.4% in Group I patients.

through the azygos vein. Only two children required revision of the baffle to relieve SVC stenosis.

IVC stenosis was identified in three (0.9%) of the 316 early survivors: two in Group I and one in Group II. One child had mild IVC stenosis but two required repair.

Partial obstruction of pulmonary venous channels was encountered in 12 (3.8%) of the 316 early survivors. In six children (4 in Group I, 2 in Group II), all of whom died, stenosis occurred at the plane of the original atrial septum, the baffle apparently adhering to the area of septal excision and then contracting to obstruct venous return from all four veins. In the other six children (2 in Group I, 4 in Group II), the stenosis was more posterior in the left atrium, between the entrance of the right and left pulmonary veins, obstructing only the left pulmonary veins. Five of these children survived repair but one died later. Ostial stenosis of the pulmonary veins was found at reoperation in six children with pulmonary venous obstruction, and was not only difficult to repair but persisted in all. Ostial stenosis of the left pulmonary veins, with no apparent preceding cause, was found at the time of the Mustard operation in two other children.

In total, there were 81 baffle "problems" identified among the 316 early survivors of the Mustard operation. Although most were minor in nature, 14 (4.4%) children required reoperation and there were nine deaths: four after reoperation and five without reoperation.

Other Complications

At late cardiac catheterization (126 cardiac catheterization studies) other problems were noted. Left ventricular outflow tract stenosis with a left ventricular–pulmo-

nary artery (LV–PA) gradient over 10 mmHg was found in 24 children. This was mild in 19 children with a gradient less than 26 mmHg. The other five children had a gradient ranging from 26 to 58 mmHg. Thirteen children were found to have pulmonary hypertension. In five children this was related to obvious problems; pulmonary venous obstruction (2), pulmonary vein thrombosis (1), recurrent chest problems (1), and pulmonary vein stenosis (1), and all five children subsequently died. Seventeen children had a small VSD that had been ignored intentionally at the time of Mustard repair.

Postoperative Rhythm Status

Late electrocardiographic follow-up at least 1 year after operation was available in 225 children of whom 150 (66.7%) were in sinus rhythm (Table 5). Of 41 Group I patients, 21 (46.7%) were in sinus rhythm. In Group II, 92% were in sinus rhythm at the time of discharge from the hospital and 129 (71.7%) of 180 children were in sinus rhythm by last electrocardiogram. Pacemakers were inserted in seven children, four in Group I and three in Group II. In five children the pacemakers were required for sick sinus syndrome and in two children pacemakers were required for SA/AV node dysfunction.

The discharge electrocardiograms of 39 patients who had Blallock-Hanlon septectomy between 1981 and 1984 were reviewed. Although 35 patients were in normal sinus rhythm, four showed abnormalities of rhythm, junctional rhythm, sick sinus syndrome, first degree A-V block, and low atrial pacemaker, respectively. Electrocardiograms just before Mustard repair revealed a similar incidence of rhythm problems predating repair.

A total of 216 Holter recordings were obtained after Mustard repair in 126 patients (Table 6). These included 23 Group I patients (35 recordings) and 103 Group II patients (181 recordings). The mean interval between operation and Holter recording was 148.4 months for Group I and 27.3 months for Group II. Although sinus rhythm was witnessed in 114 patients (90.5%), it was by no means the predominant rhythm exhibited in this series. The predominant cardiac rhythm was a junctional bradycardia or atrial flutter in 60% of Group I patients and 52% of Group II patients. Among the 40% of Group I children in a predominantly atrial rhythm (including sinus), three had a wandering atrial pacemaker and four had bursts of supraventricular tachycardia (SVT). Similarly, among the 48% of Group II children with a predominant atrial rhythm, 19 had a wandering atrial pacemaker and seven had SVT. A variety of ventricular arrhythmias were seen in both groups of patients, including ventricular tachycardia.

TABLE 5. *Postoperative Rhythm: Last EKG*

	Group I (1963–1973)	Group II (1974–1985)	Total
Sinus rhythm	21 (46.7%)	129 (71.7%)	150 (66.7%)
Junctional rhythm	6 (13.3%)	33 (18.3%)	39 (17.3%)
Sick sinus syndrome*	10 (22.2%)	6 (3.3%)	15 (6.7%)

Atrial flutter	6 (13.3%)	3 (1.7%)	9 (4.0%)
SA/AV node dysfunction*	2 (4.4%)	2 (1.1%)	5 (2.2%)
Total	45	180	225

* Includes seven patients with pacemakers.

Twenty-two children had multicatheter EPS an average of 52.5 months after operation (Table 7). There were four patients from Group I and 18 from Group II; four studies were indicated to investigate symptomatic rhythm disturbances, whereas the other 18 were considered "routine" postoperative investigations. It is clear that sinus node function was frequently suppressed in this group of patients and some demonstrated subtle abnormalities of A-V node function.

To determine whether the EKG and EPS changes after the Mustard operation were progressive or detectable at the time of the procedure, 23 children were studied prospectively with preoperative baseline catheter EPS, followed by EPS on postoperative days 1, 3, and 8, performed at the bedside using routinely placed epicardial temporary pacing wires (Table 8). The only EPS abnormalities before operation pertained to the sinus node and atrial muscle function of children with a prior Blalock-Hanlon septectomy. By contrast, abnormal studies were frequent after the Mustard operation, with the majority of these changes persisting to day 8.

RV Function

A subjective estimation of RV contractility was made by the radiologist and/or the cardiologist from the RV angiograms of 126 children with isolated TGA (Table 9). Forty-two children appeared to show some alteration in RV contractility but in only 14 of 126 (11%) children was this considered definite and rated as moderate (10) or severe (4) diminution in RV contractility. Subsequently two children died of cardiac failure. Thirteen (10.3%) of the 126 children had mild tricuspid incompetence, four with and nine without obvious RV dysfunction. Eight of the children with RV dysfunction were in Group I and six were in Group II. The difference in incidence is not significant by actuarial analysis (p = 0.076).

Fourteen Group I patients underwent supine radionuclide bicycle exercise with estimation of RV ejection fraction.[14] At rest, the RV ejection fraction averaged 46 ± 11% with no significant change at peak exercise, 48 ± 12%. Additionally, there was an inappropriate response of blood pressure, rising only 18 ± 15% of resting values. The cardiopulmonary response to exercise was studied in 17 asymptomatic Group I patients during upright bicycle exercise. During incremental increase in work, the TGA patients, as compared with age-matched controls, had lower work capacities, heart rates, and oxygen consumptions, but minute ventilation was normal. Cardiac output was within the normal range at 50% maximal stress, thus suggesting reduced aerobic capacity for exercise.

TABLE 8. *Cardiac Rhythm after Mustard Operation: Acute Perioperative EPS Changes*

TV incompetence alone	4	5

Clinical Status

Of 148 patients for whom adequate information on clinical status was available, 113 (76%) were in NYHA Class I and 35 (24%) were in Class II (Table 10). None were in Class III or IV. Information regarding medication was obtained in 167 patients. Seventy-nine per cent were not receiving any medication. Thirty-one patients were receiving digitalis for dysrhythmia management. One patient was receiving digitalis and diuretic for fluid retention. Two children were taking inderol for dysrhythmia and one patient was receiving nitroglycerin for intermittent chest pain associated with dysrhythmia. No surviving patients were in uncontrolled congestive heart failure.

Information regarding school and work experience indicated a performance similar to that found in children after other cardiac operations. Most of the 169 patients reviewed were at school or employed. One hundred fifteen children were in an appropriate school grade, eight attended college, and five were considered exceptional students. Thirty-seven children had repeated at least one grade at school and seven patients required special education classes. There were 15 patients with neurologic abnormalities after surgery: hemiparesis (7), mental retardation with seizure disorder (4), cerebral palsy (1), and other seizure disorders (3). In 10 of the 15 children, the neurologic abnormality

No cardiac medication	28	104	132 (79%)

preceded the transposition repair, but in the other five children the problem seemed related to the operation, although in two cases it was not noted for several months.

Discussion

There has been a notable decline in the early mortality with the Mustard operation in isolated TGA until it is now virtually zero with no deaths in the last 160 patients operated on since January 1978. Other authors have also reported very low mortality.[15-20] Late mortality has also decreased with 10 deaths in the 221 early survivors since January 1974, giving a 10-year survival rate of 93.7%. Statistical comparison with our earlier experience indicates that this is significant ($p = 0.025$). The reason for the improvement can only be surmised to include more efficient and effective operation, improved myocardial protection, and improved postoperative management of dysrhythmias and other complications.

Baffle complications have been reported frequently[15,17,20-25] and they continue to occur, although perhaps at a slightly lower rate. Certainly it is our impression that baffle leaks are less frequent, although still the most common of the baffle complications. Serious degrees of SVC obstruction are less frequent but mild SVC stenosis has been seen more often since 1974, when we began leaving a ridge of atrial septum between the SVC and the tricuspid valve to reduce rhythm disorders. Similarly, stenosis of the IVC channel is seldom seen and there have been no new instances of this complication for many years. To prevent caval stenosis we use a pericardial baffle that is moderately redundant at both caval orifices, and suture carefully to avoid leaks that might allow contraction of the baffle and narrowing of the caval channel.

Narrowing of the pulmonary venous channel is a serious complication.[23-25] In recent years obstruction affecting both right and left veins at the level of the original atrial septum has been less frequent than earlier years. Obstruction of the left pulmonary veins occurred in six children and appears to result from placing the upper and lower baffle suture lines too close to each other, on the posterior wall of the left atrium, a maneuver intended to enlarge the caval channels. Of 316 early survivors of the Mustard operation for simple TGA, 19 (6.0%) children had baffle complications that required reoperation or caused death. Possibly impeccable operative techniques would reduce this problem further, but some risk of these complications appears inherent to the procedure. In general, a moderately redundant baffle seems to work well, and the most important detail seems to be the position and integrity of the baffle suture line.

Dysrhythmias, the most frequent problem after the Mustard operation, accounted for late death in nine patients and are assumed to be the cause in four other patients who died suddenly. Ten (10/95) of these 13 deaths were in Group I patients and the other three (3/221) were in Group II patients. The primary problem is sinus node dysfunction, and atrioventricular conduction is usually intact.[13] Our overall results from analysis of the last electrocardiogram at least 1 year after operation revealed that 66.7% of children were in sinus rhythm, whereas the remainder demonstrated evidence of sinus node dysfunction, junctional rhythm, or in a few cases more serious problems such as atrial flutter or AV node dysfunction. In our earlier report we noted that a change in technique, which preserved a ridge of atrial septum between the SVC and TV, increased the incidence of sinus rhythm.[10] Indeed, the incidence of sinus rhythm was greater in Group II patients than in the earlier group. Several authors[26,27] suggest, however, that the incidence of dysrhythmia increases with time; therefore, perhaps the improvement will not last. Stark et al. found 59% with normal sinus rhythm on 24-hour monitoring 2 weeks after repair.[28] Bierman et al.[29] in a series that included complex TGA reported only 30% of patients free of arrhythmias 9 years after repair, but symptoms from rhythm or conduction disturbances were rare. In our experience only about one quarter of children with abnormal rhythms are symptomatic. Also, this information should be kept in perspective for even after simple ASD repair normal sinus rhythm was found in only 78% of patients.[30]

The data derived from the Holter and EPS studies is also less optimistic for it appears that stable sinus rhythm is less frequent than previously believed. Despite the technical changes in operative technique designed to preserve the sinus node, there is no appreciable difference in the prevalence of arrhythmias on Holter recordings from patients repaired before and after these modifications. Moreover, the comparable occurrence rates of arrhythmias on Holter tapes for Groups I and II, despite the large difference in mean postoperative intervals (148.3 months *vs.* 27.3 months, respectively) suggest that the appearance of rhythm disturbances may not be as progressive as suggested by others.[26,27] This notion is supported by the results of our prospective study in 23 children with perioperative EPS. These children will be the subject of ongoing surveillance, but it is interesting that the prevalence of their early postoperative EPS abnormalities is so similar to that of the other group studied an average of 52.5 months after surgery to suggest that the conduction system abnormalities caused by the Mustard operation are detectable early after surgery, even if the clinical manifestations appear later. The ongoing problems with persistent or recurring atrial flutter, pacemaker dependency, and other dysrhythmias confirm that cardiac rhythm disorders represent a major shortcoming of the Mustard operation.

Postoperative RV function has also been a concern to everyone dealing with TGA patients. Early death and myocardial failure are infrequent now and most children do not require inotropic support after operation. However, the details of management, particularly duration of myocardial ischemia, are important. It is our impression that when repair is done on infants less than 3 months old, there is an increased incidence of myocardial failure and need for inotropic support. By comparison, an infant or child having an arterial switch repair seems to accept a relatively long period of myocardial ischemia. It seems that the right ventricle cannot tolerate the same duration of myocardial ischemia as the left ventricle and still support systemic pressures. Cardiac failure was the cause of late death in five of 31 children with simple TGA and the most common cause of late death in complex TGA. It likely results from the cumulative effect of all the damaging events that influence the right ventricle before, during, and after the repair. This may include not only the obvious effect of any myocardial ischemic interval but also the insidious effects of various events associated with less than optimum myocardial perfusion, such as a low output state after operation or an abnormal cardiac rhythm with bradycardia or tachycardia. Furthermore, that most late deaths occurred within 4 years of repair suggests a relationship to the operation. There was only one late death of cardiac failure more than 4 years after operation.

We have attempted to detect abnormalities of RV contractility from the angiographic appearance at cardiac catheterization, but unfortunately this subjective grading does not provide an accurate measurement. Although some alteration in RV contractility was suspected in almost one third of the 126 children who had late cardiac catheterization with angiocardiography, only 14 (11%) showed definite RV dysfunction. Two children died subsequently but the others have remained asymptomatic. More objective evaluation in a small cohort of Group I patients suggested impairment in the ability of the RV to function appropriately under the stress of exercise as compared with normals.[14]

There have been many studies of RV function after atrial repair of TGA and the ultimate significance is still not clear. Abnormal size and ejection fraction of the RV after atrial repair was noted.[31-33] Using gated equilibrium nuclear angiography, Benson et al.[14] evaluated the RV function response to the stress of supine bicycle exercise an average of 6.4 years after the Mustard operation. Although clinically well, 11 of 19 children had an abnormal response with a decrease or at least no increase in RV ejection fraction. Similar results were obtained by others.[34-36] Parrish et al.[37] also noted an abnormal left ventricle (LV) repsonse to exercise in 10 of 11 children tested after a Mustard repair and concluded that biventricular dysfunction was frequently present. In each study some children had normal RV function at rest and during exercise, which suggests that the RV problem may not be inevitable. Indeed, Benson et al.[38] recently reported normal systemic ventricular function in patients with congenitally corrected TGA. Ramsay et al.[39] found an abnormal response to exercise by both RV and LV after Mustard repair but found no predictable correlation with clinical or hemodynamic criteria. Graham and co-workers,[40] comparing groups of patients after atrial repair of simple TGA, found an improvement in the postoperative RV ejection fraction in patients operated on after 1974, whether by Mustard or Senning technique compared with patients operated on previously. They suggest that this improvement may be due to a younger age at surgery and/or changes in operative technique, particularly myocardial protection. Smith et al.,[41] however, caution that the general architecture of the ventricular mass and the atrioventricular valves is different from normal and the function of the normal heart may not always be an appropriate yardstick for comparison.

Tricuspid valve incompetence was not a major problem. It was found in only 13 (10%) children who had cardiac catheterization after operation, four in association with RV dysfunction. Tricuspid valve incompetence is more common in children who have had repair of an associated VSD,[24] undoubtedly due to distortion of the valve by the repair in some cases. Occasionally the tricuspid incompetence is present before repair.[36] Deal et al.[42] found tricuspid valve abnormalities were frequent in patients with TGA and VSD but were rare in isolated TGA. Tynan et al.[43] reported postoperative tricuspid incompetence secondary to arrhythmia in some patients. Thus, the tricuspid incompetence in children after simple TGA repair appears to be related to either RV dysfunction, arrhythmia, or in rare cases pre-existing tricuspid valve abnormalities.

The general clinical status of most patients is good. Almost all patients exhibit normal growth after repair.[20,21] In our series 76% were in NYHA Class I and 24% in NYHA Class II. Although 79% were not taking cardiac medications, 21% were, nearly all for dysrhythmia management. Although it is our impression that these children are not generally athletic, most are unrestricted and some take part in athletic events. Stark et al.[28] found that exercise performance of asymptomatic patients who appeared to be living normal lives 6–13 years after Mustard's operation was somewhat diminished compared with a group of normal children, as our cardiopulmonary exercise testing has also shown. There was no significant difference between the group of patients who had their Mustard operation in infancy and later. Mathews et al.[44] conducted exercise studies in children after Mustard repair and found that, although no patients had subjective exercise intolerance before the test, the exercise tolerance was decreased in half, with maximum oxygen consumption values lower than controls.

This paper is not intended to compare in detail our results with the Mustard procedure with those of others. Indeed it would be difficult to do so effectively for we have focused on children with simple transposition, to present a clearer picture since the incidence of dysrhythmia, tricuspid incompetence, and RV dysfunction is higher after repair of TGA with VSD. Similarly we have deliberately avoided comparing the Mustard and Senning operations. Many authors have reported excellent results with the Senning procedure[45–47] but there are few long-term series for comparison. We believe that there is little difference in the results of the two procedures and that most of the complications and problems encountered after the Mustard procedure will also occur with the Senning operation.

Our main purpose in this presentation has been to describe the early and late results of the Mustard procedure and indicate both the current status and the improvements that have occurred. With this information the comparison with arterial switch repair can be made on a more rational basis. Arterial repair in the newborn, a technically demanding procedure, has been performed with low risk by some surgeons.[7–9,48] Interim problems and the need for repeat operations are as common if not more common than after the Mustard operation in our experience. The main appeal of arterial repair is the expected low incidence of major late complications such as dysrhythmias, tricuspid incompetence, and RV dysfunction, which may lead to late morbidity and death. The chief concern is whether the early results of a few surgeons can be reproduced by others without excessive risk. We hope this paper presents a fair summary of what atrial repair can offer the infant with simple TGA.

Acknowledgments

The authors thank Dr. Jane Heggie for the telephone follow-up of many of these patients and Valerie Daniels for her skilled assistance in preparing the manuscript.

BURN FELLOWSHIP

The New York Hospital-Cornell Medical Center Burn Center is a modern burn treatment facility with 24 intensive care beds and annual admissions of 850 in-patients and 3,000 out-patients. During the year's experience, the Fellow will be responsible for the surgical critical care of all burned patients, for house officer education, and for participation in original and on-going clinical research protocols. The Burn Center is the recipient of an NIH Burn Research Center Grant and supports comprehensive laboratories with state-of-the-art instrumentation and active investigators in the fields of wound healing, immunology, metabolism, nutrition, and cardiopulmonary response to injury. An additional year in the laboratory may be elected by the Fellow. Candidates preferably should be Board eligible in General Surgery, but we will strongly consider academically oriented senior surgical residents from university programs incorporating the Fellowship as part of their training programs. Send inquiries to:

Cleon W. Goodwin, M.D.
New York Hospital-Cornell Medical Center

38th Postgraduate Course and Annual Meeting of the

AMERICAN ASSOCIATION FOR THE STUDY OF LIVER DISEASES

"Advances in Hepatobiliary Disease Seen in Practice"

October 25-28, 1987
Chicago Marriott Hotel, Chicago, Illinois

The American Association for the Study of Liver Diseases (AASLD) announces its 38th Annual Postgraduate Course entitled "Advances in Hepatobiliary Disease Seen in Practice" to be held at the Chicago Marriott Hotel on Sunday, October 25 and Monday, October 26, 1987. The course will be followed by the 38th Annual Meeting of the American Association for the Study of Liver Diseases on October 27-28, 1987.

Director of the course is Dr. David H. Van Thiel, Vice President of the AASLD. On Sunday, October 25, chronic cholestatic liver disease and primary hepatocellular carcinoma will be discussed. The second day, an extensive review of complications of chronic liver disease and biliary stone disease will be presented. At noon, the traditional Meet-the-Professors luncheons are scheduled for course participants to meet with experts in the field of hepatology in an informal small group forum. The course is designed to present the newest concepts in the etiology, pathogenesis, diagnosis and management of chronic liver diseases which are seen commonly in clinical practice. The emphasis will be on new diagnostic and therapeutic modalities including the value of liver transplantation as applied to these particular problems. Participants will have an opportunity to meet and speak with experts in the fields of hepatology, immunology, virology, hepatobiliary and liver transplant surgery.

Fee:	**AASLD Members**	**$140.00**
	Nonmembers	**$225.00**
	Trainees	**$100.00**
	Luncheon	**$ 20.00**

CME Credit: 16 hours

Weck introduces tw
to make you throw away a

On the left is the lever-action VisiStat® stapler. On the right is the pistol-grip Weck 360LX stapler. Both were designed to give you the best features of other skin staplers, without their disadvantages.

Both are members of the new Weckstat™ line of premier closure products, so you can now order the two most popular stapler styles from one source. And dispose of all the others for good.

VisiStat® stapler. The first lever-action stapler to combine superior visibility with reliable control.

While other lever-action staplers can either block your vision or hamper control, the new VisiStat® stapler enhances both.

The angle of the stapler head and position of the staple-forming anvil are designed to give you the clearest possible view of the staple during formation. The firing action is extraordinarily smooth and controlled, with no jarring recoil.

WECK

Members of the Weckstat™ family of closure product

© 1986, Edward Weck & Co., Inc., P.O. Box 12600, Research Triangle Park, NC 277

disposable staplers designed the others. Forever.

And the NonStop™ staple feed is designed for maximum reliability, closure after closure.

Get precise control of staple placement with the high-visibility Weck 360LX® stapler. While other pistol-grip staplers can make staple placement difficult to control, the Weck 360LX® stapler makes it easy.

The head of the stapler rotates 360° on a centered axis for access to hard-to-reach areas. The L-shaped handle has an ideal trigger span for control of staple closure. Staples are clearly visible as they form to further enhance accuracy of placement. And the Weck 360LX® stapler is the *only* pistol-grip style with a straight-stack feeding mechanism for reliable staple delivery. So whether you prefer a pistol-grip or a lever-action stapler, the only name you need to remember now is Weck. For details, contact your Weck Representative or call (800) 334-8511.

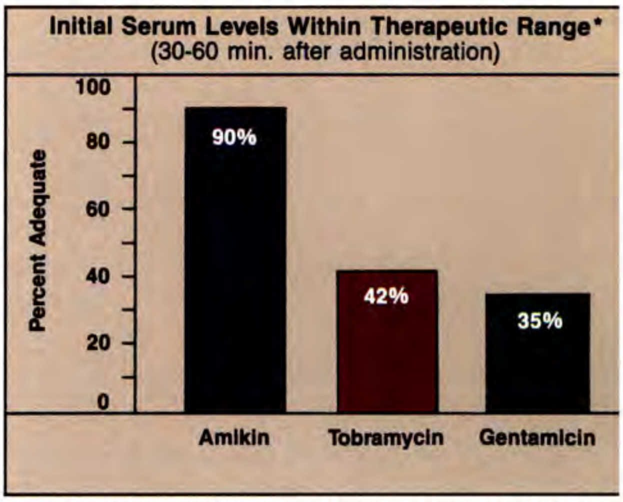
IN EMPIRIC THERAPY OF NOSOCOMIAL INFECTIONS

Peace of mind. Right from the start.

When infection develops in the hospitalized patient, there's no time to be wrong. Amikin® (amikacin sulfate) delivers the aggressive First-Dose therapy that can save lives.

First-Dose Predictability.

After the first dose, Amikin produces therapeutic blood levels that are more predictable than those of the other amino glycosides.[1]

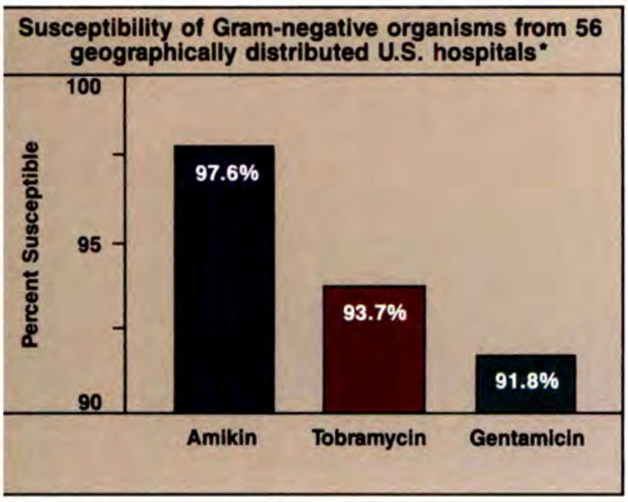


*Adapted from Holloway WJ: Management of sepsis in the elderly. *Am J Med* 80 (su 6B): 143-148, 1986.

BRISTOL®
NDC 0015-3020-20
Amikin®
AMIKACIN SULFATE
INJECTION For I.M. or I.V. Use
EQUIVALENT TO
500 mg AMIKACIN Per 2 ml
CAUTION: Federal law prohibits dispensing without prescription.
20
30
40

First-Dose Antimicrobial Activity.

Amikin has the broadest spectrum of any aminoglycoside.[2]



otal Amikin isolates = 247,503

n vitro data may not be directly correlated to clinical effectiveness. Data on file, Bristol Laboratories.

First-Dose Synergy.

In combination with antipseudomonal penicillins and latest generation cephalosporins, Amikin is overall the most synergistic of the aminoglycosides.[3,4]

First-Dose Economy.

The least expensive aminoglycoside is not necessarily the one with the lowest acquisition cost. It's the one *not* requiring replacement with a more effective agent.[5]

AMIKIN®
AMIKACIN SULFATE

BRIEF SUMMARY OF PRESCRIBING INFORMATION (1) 10/83
For complete prescribing information, please consult product literature.

WARNINGS

Patients treated with aminoglycosides should be under close clinical observation because of the potential ototoxicity and nephrotoxicity associated with their use.

Ototoxicity, both auditory and vestibular, can occur in patients treated at higher doses or for periods longer than those recommended. The risk of amikacin-induced ototoxicity is greater in patients with renal damage. High frequency deafness usually occurs first and can be detected only by audiometric testing. Vertigo may occur and may be evidence of vestibular injury.

The ototoxicity potential of amikacin in infants is not known. Until more safety reports become available, amikacin should be used in infants only in those specific circumstances when susceptibility testing indicates that other aminoglycosides cannot be used or are otherwise contraindicated, and when the infant can be observed closely for evidence of toxicity.

Aminoglycosides are potentially nephrotoxic. Renal and eighth-nerve function should be closely monitored in patients with known or suspected renal impairment and also in those whose renal function is initially normal but who develop signs of renal dysfunction during therapy. Such impairment may be characterized by decreased creatinine clearance, the presence of cells or casts, oliguria, proteinuria, decreased urine specific gravity or evidence of increasing nitrogen retention (increasing BUN or creatinine).

Evidence of impairment in renal, vestibular or auditory function requires discontinuation of the drug or dosage adjustment.

Serum concentrations should be monitored when feasible, and prolonged peak concentrations above 35 mcg/ml should be avoided. Urine should be examined for increased excretion of protein, the presence of cells and casts, and decreased specific gravity.

Concurrent and/or sequential use of topically or systemically neurotoxic or nephrotoxic antibiotics, particularly kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin should be avoided.

AMIKIN should not be given concurrently with potent diuretics (ethacrynic acid, furosemide, meralluride sodium, sodium mercaptomerin or mannitol). Some diuretics themselves cause ototoxicity, and intravenously administered diuretics enhance aminoglycoside toxicity by altering antibiotic concentrations in serum and tissue.

CONTRAINDICATIONS

A history of hypersensitivity to amikacin is a contraindication for its use.

WARNINGS

See "Warning" box above.

PRECAUTIONS

AMIKIN is potentially nephrotoxic, ototoxic, and neurotoxic. The concurrent or serial use of other ototoxic or nephrotoxic agents should be avoided either systemically or topically because of the potential for additive effects. Such agents include antibacterial drugs such as kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin as well as certain diuretic agents such as ethacrynic acid or furosemide.

Ototoxicity — See "Warning" box.

Nephrotoxicity — Since AMIKIN is present in high concentrations in the renal excretory system, patients should be well hydrated to minimize chemical irritation of the renal tubules. Kidney function should be assessed by the usual methods prior to starting therapy and daily during the course of treatment.

If signs of renal irritation appear (casts, white or red cells or albumin), hydration should be increased. A reduction in dosage (see "Dosage and Administration") may be desirable if other evidence of renal dysfunction occurs such as decreased creatinine clearance, decreased urine specific gravity, increased BUN, creatinine or oliguria. If azotemia increases or if a progressive decrease in urinary output occurs, treatment should be stopped.

Note: When patients are well hydrated and kidney function is normal the risk of nephrotoxic reactions with amikacin is low if the dosage recommendations (see "Dosage and Administration") are not exceeded.

Neurotoxicity — Neuromuscular blockade and muscular paralysis have been demonstrated in the cat with high doses of amikacin (188 mg/Kg). The possibility of neuromuscular blockade and respiratory paralysis should be considered when amikacin is administered concomitantly with anesthetic or neuromuscular blocking drugs. If blockade occurs, calcium salts may reverse this phenomenon.

Other — Cross-allergenicity among aminoglycosides has been demonstrated. As with other antibiotics the use of amikacin may result in overgrowth of nonsusceptible organisms. If this occurs, appropriate therapy should be instituted.

Pregnancy — Reproduction studies have been performed in rats and mice and have revealed no evidence of impaired fertility or harm to the fetus due to amikacin. There are no well-controlled studies in pregnant women but investigational experience does not include any positive evidence of adverse effects on the fetus. Although there is no clearly defined risk, such experience cannot exclude the possibility of infrequent or subtle damage to the fetus. AMIKIN should be used in pregnant women only when clearly needed.

It is not known whether this drug is excreted in human milk. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

ADVERSE REACTIONS

Ototoxicity — See "Warning" box.

Nephrotoxicity — Albuminuria, presence of red and white cells, casts, azotemia and oliguria have been reported.

Other — In addition to those described above, other adverse reactions which have been reported on rare occasions are skin rash, drug fever, headache, paresthesia, tremor, nausea and vomiting, eosinophilia, arthralgia, anemia, hypotension.

Overdosage — In the event of overdosage or toxic reaction, peritoneal dialysis or hemodialysis will aid in the removal of amikacin from the blood.

"I'D LIKE TO MAKE AN APPOINTMENT WITH THE DOCTOR"

Be prepared, Doctor. More patients will be asking about colorectal cancer. According to a survey* conducted by the American Cancer Society, many people would like to receive more information about colorectal cancer, and 83% said they would want to be checked for it. Further, they are learning that this cancer can be detected *before* symptoms appear. The present cure rate is 44%. The cure rate *could* be as high as 75%, with early detection and appropriate management.

For asymptomatic persons the Society recommends annual digital rectal examination at age 40 and over; at age 50 and over, an annual stool blood test, as well as sigmoidoscopy every three to five years, following two initial annual negative sigmoidoscopies.

We're here to help. You can reach us at your local American Cancer Society office or write to our Professional Education Department at National Headquarters, 90 Park Avenue, New York, N.Y. 10016. Ask about the Society's Colorectal Check program of professional and public education for the early detection of colorectal cancer.

Shunt Surgery *Versus* Endoscopic Sclerotherapy for Long-term Treatment of Variceal Bleeding

Early Results of a Randomized Trial

LAYTON F. RIKKERS, M.D., DAVID A. BURNETT, M.D., GARY D. VOLENTINE, M.D.,
KENNETH N. BUCHI, M.D., and ROBERT A. CORMIER, R.N.

From the Departments of Surgery and Medicine, University of Nebraska Medical Center, Omaha, Nebraska, and University of Utah School of Medicine, Salt Lake City, Utah

In September 1982, a prospective randomized trial comparing shunt surgery and endoscopic sclerotherapy for the elective management of variceal hemorrhage in patients with cirrhosis was initiated. Twenty-seven patients have received shunts (distal splenorenal = 23, nonselective = 4) and 30 patients have had chronic sclerotherapy. Eighty-six per cent of patients had alcoholic cirrhosis and 33% were Child's class C. After a mean follow-up of 25 months, 19% of shunt and 57% of sclerotherapy patients have had rebleeding (p = 0.003). Kaplan-Meier survival analysis reveals similar 2-year survival rates for shunt (65%) and sclerotherapy (61%) groups. Only two of 10 sclerotherapy failures have been salvaged by surgery. Posttherapy quantitative hepatic function, frequency of encephalopathy, and cumulative medical costs were similar for both groups. Hepatic portal perfusion and portal pressure at 1 year were better maintained by sclerotherapy than by distal splenorenal shunt. In conclusion, endoscopic sclerotherapy and shunt surgery provide similar results with respect to survival, hepatic function, frequency of encephalopathy, and costs. Sclerotherapy is an acceptable, but not superior, alternative to shunt surgery for treatment of variceal hemorrhage.

THE IDEAL THERAPY for variceal hemorrhage would permanently eliminate this life-threatening complication of portal hypertension and have no adverse effects on hepatic physiology. Unfortunately, no single treatment provides both of these advantages. Surgical portal decompression reliably prevents future bleeding episodes, but alters liver perfusion. Endoscopic sclerotherapy and nonshunting operations minimally influence hemodynamic function, but are generally followed by a higher frequency of recurrent hemorrhage than portal-systemic shunts.

The distal splenorenal shunt (DSRS) is the only commonly used shunting procedure with the capacity of maintaining hepatic portal perfusion. Several controlled trials[1-3] comparing the DSRS to various nonselective shunts have demonstrated a lower frequency of encephalopathy after selective variceal decompression. Based on these studies, as well as other large uncontrolled series,[4,5] the DSRS has emerged as the preferred procedure for most patients when surgical therapy is indicated for variceal hemorrhage. Because some patients, *e.g.*, those with medically intractable ascites, are not candidates for the DSRS, we have evolved a selective operative approach, selecting the type of shunt (DSRS, end-to-side portacaval shunt, or side-to-side portal-systemic shunt) based on each individual's clinical and hemodynamic circumstances.[6]

Because of dissatisfaction with portal decompression and its adverse consequences of encephalopathy and hepatic failure, endoscopic sclerotherapy was reintroduced in the 1970s, first for the emergency management of bleeding varices and subsequently as definitive treatment to prevent recurrent hemorrhage. Several controlled trials[7-10] of sclerotherapy *versus* conventional medical management have shown a beneficial effect of this treatment on frequency of rebleeding, and some trials[7,9] have demonstrated prolonged survival after sclerotherapy.

The current investigation was designed to determine whether shunt surgery (selective approach) or chronic endoscopic sclerotherapy is preferable for patients with cirrhosis who bleed from varices. Only patients who survived their initial hemorrhage are included. Thus,

elective rather than emergency therapies are compared. Based on previous controlled studies of treatments for variceal hemorrhage in predominantly alcoholic cirrhotic populations, it was anticipated that these two therapies might result in similar survival rates. Therefore, multiple variables were carefully studied to determine the relative impact of these treatment modalities on hepatic functional reserve, hepatic hemodynamic status, psychoneurologic function, and medical costs.

Methods

Patients

The study population comprised 57 patients with cirrhosis and variceal hemorrhage referred between September 1982, and December 1986. During the first 2 years, patients were accrued from the University of Utah Medical Center (N = 18) and Salt Lake Veterans Administration Medical Center (N = 17). After the principal investigator moved to the University of Nebraska Medical Center in August 1984, study patients were derived from that institution (N = 10) and from the Omaha Veterans Administration Medical Center (N = 12). The study population was drawn from a pool of 150 patients who were treated for variceal hemorrhage by surgery or endoscopic sclerotherapy at these four hospitals during these intervals. To be considered for randomization, each patient had to meet the following criteria: (1) historic, clinical, and/or laboratory evidence of cirrhosis (diagnosis confirmed by biopsy in all patients); (2) endoscopic documentation of acute or recent variceal hemorrhage (actively bleeding varix or large nonbleeding varices with no other lesions) requiring at least three units of blood transfusion; (3) residence within 500 miles of Salt Lake City or Omaha; (4) cessation of acute variceal hemorrhage either spontaneously or by use of one or a combination of intravenous vasopressin infusion, balloon tamponade, and emergency endoscopic variceal sclerosis; and (5) patency of the splanchnic venous system demonstrated by visceral angiography. Patients bleeding from gastric varices located more than 2 cm from the esophagogastric junction were excluded. After stabilization from the acute bleeding episode, patients who met the above criteria and who agreed to participation after informed consent were randomized using Efron's biased coin design,[11] based on three liver function strata (modified Child's classification) and type of hospital (University or Veterans Administration). Twenty-eight patients were randomized to shunt surgery and 29 patients were randomized to endoscopic sclerotherapy. One patient refused surgery and was treated with endoscopic variceal sclerosis. In all subsequent analyses, this individual is included in the sclerotherapy group (N = 30; shunt group, N = 27).

Therapy

Selection of shunt was based on each individual's clinical circumstances and hepatic hemodynamic status.[6] Patients with compatible anatomy (splenic vein greater than 7 mm), hepatopetal portal flow on preoperative angiography, and either absent or medically controllable ascites received the DSRS (N = 23). Individuals with ascites intractable to medical management or spontaneous reversal of portal flow on preoperative angiography had a side-to-side portal-systemic shunt (N = 3). Side-to-side shunts used included the side-to-side portacaval shunt (N = 1) and Dacron graft (16–20 mm) interposition shunts (N = 2) in the portacaval or mesorenal positions. A single end-to-side portacaval shunt was done emergently in a patient who massively rebled after randomization. All shunts were constructed by a single surgeon (LFR).

Endoscopic sclerotherapy was performed with a standard upper gastrointestinal flexible endoscope without accessories. During the first 2 years of the investigation, 0.75% sodium tetradecyl sulfate in 50% dextrose was used as sclerosant because 5% sodium morrhuate, which has been used during the last 2 years, was not then available. Intravariceal injections of all columns just above and at 5 cm proximal to the esophagogastric junction were accomplished at the initial session. Approximately 2 mL of sclerosant per injection with a maximum of 20 mL per session was used. Sclerotherapy was repeated at 4- to 6-day intervals until most varices were eradicated. Follow-up endoscopy was scheduled for 4–6 weeks after the last session and then at 6-month intervals unless recurrent hemorrhage intervened. The 30 sclerotherapy patients had 6.7 ± 0.8 SEM sclerosis treatments per patient with a range from 1 to 23 treatments. Eighty per cent of patients were compliant and returned for endoscopy as scheduled. Varices were completely eradicated in 19 patients (63%), but reformed in 12 of these individuals. The only major complication of sclerotherapy was esophageal stricture in three patients, all of whom were successfully dilated. Sclerotherapy was done under the supervision of a single endoscopist at each hospital.

Death of any cause was considered failure of therapy in both groups. Shunt surgery was also considered a failure when shunt thrombosis developed and sclerotherapy was initiated because clinical circumstances or anatomy precluded further surgery. Sclerotherapy failure was defined as change to surgery necessitated by recurrent hemorrhage despite repeated sclerosis sessions. The decision for surgical intervention was made by the individual gastroenterologist and not based on a specific number or degree of severity of recurrent bleeding episodes.

Pretherapy and Post-therapy Evaluations

All patients had an extensive pretherapy evaluation. In addition to routine post-therapy follow-ups at 3–6-month intervals, comprehensive evaluations were completed at 1 year (shunt = 17; sclerotherapy = 17) and 3 years (shunt = 5; sclerotherapy = 7) after shunt surgery or initiation of sclerotherapy. Patients not seen in person were interviewed by telephone. After August 1984, one of the authors (RAC) returned to Salt Lake City to conduct 1- and 3-year evaluations. One sclerotherapy patient has been lost to follow-up.

Routine clinical and laboratory examinations. Physical examination was directed toward detection of ascites and encephalopathy. Episodes of recurrent hemorrhage, employment status, and presence or absence of continuing alcoholism were recorded. Routine laboratory tests included hematocrit, white blood cell count, platelet count, prothrombin time, partial thromboplastin time, serum albumin, total bilirubin, alkaline phosphatase, AST (SGOT), ALT (SGPT), blood urea nitrogen, and creatinine.

Hepatic hemodynamic variables. Hepatic hemodynamic variables were assessed by visceral angiography, measurement of corrected sinusoidal pressure (CSP), and quantitation of effective hepatic blood flow (EHBF) by a low-dose galactose clearance technique. The portal perfusion grade (PPG) was qualitatively determined from the venous phase of the selective superior mesenteric angiogram (grade 1 = good hepatopetal portal flow to grade 4 = absent flow).[12] Preoperative studies (including left renal vein opacification) also provided essential information about splanchnic venous anatomy, and postoperative angiography determined shunt patency status. CSP was measured as hepatic venous wedge pressure minus free hepatic venous pressure. EHBF was estimated as the infusion rate of low-dose galactose (40–66 mg/min) divided by the steady-state plasma concentration of galactose as described by Henderson et al.[13]

Quantitation of hepatic function. Galactose elimination capacity (GEC) was calculated from serial venous blood samples after a bolus intravenous injection of galactose (500 mg/kg body weight).[14] Removal rate of a 5 mg/kg dose of indocyanine green (ICG) was measured from serial plasma concentrations after intravenous injection.[15] A modified Child's score was derived from serum albumin, total bilirubin, and severity of encephalopathy and ascites (Table 1).[16] Each variable was graded from 1 (best) to 3 (worst) to obtain a total score.

TABLE 1. *Determination of Child's Score*

2	3.0–3.4	1.6–2.5	Mild	Present
3	<3.0	>2.5	Moderate to severe	Tense

A = 4–5 points, B = 6–7 points, C = 8–12 points.

Psychoneurologic evaluation. An episode of clinical encephalopathy was defined as an incident of mental confusion related by the patient or a family member, or detection of disorientation by a physician. When no precipitating factors were identified, the episode of encephalopathy was considered spontaneous. Induced encephalopathy was defined as mental confusion occurring during gastrointestinal hemorrhage. Disorientation or coma appearing just before death from hepatic failure was excluded. Electroencephalograms (EEG) were graded as normal or abnormal by the criteria of Parsons-Smith.[17] The single psychometric test used was the numbers connection test.[18] Venous blood ammonia was obtained in the fasting state.

Cost analysis. Both initial and total medical costs for each therapy were calculated and compared. Initial medical costs were defined as those incurred during the hospitalization in which shunt surgery was performed or sclerotherapy initiated. Total costs included the initial hospitalization, all subsequent hospitalizations required for treatment of recurrent hemorrhage and complications of therapy or chronic liver disease, and outpatient endoscopic evaluation with or without variceal sclerosis. Only patients from the University of Utah (N = 18) and University of Nebraska (N = 10) were included in the cost analysis; all patients from the Veterans Administration Hospital were excluded.

Statistical analysis. The Kaplan-Meier method was used to plot survival and failure of therapy curves, which were compared by the log rank test.[19] Groups were compared before therapy and at 1 year and 3 years after therapy by chi-square analysis (qualitative variables) and the unpaired t-test (quantitative variables). Serial variables within a group were analyzed by the paired t-test.

Results

Pretherapy Comparison of Shunt and Sclerotherapy Groups

The shunt and sclerotherapy groups were comparable at randomization with respect to cause of cirrhosis, Child's score, quantitative hepatic function and hemodynamic variables, and measurements of neuropsychologic function (Table 2). In addition, all routine blood chemistries, coagulation variables, and hematologic indices were not significantly different between the two

groups. Based on the Child's grading system used, nine shunt (33%) and 10 sclerotherapy patients (33%) were Child's grade C.

Survival

Early mortality (within 1 month of surgery or initiation of sclerotherapy) occurred in one patient in each group. The early postoperative shunt death occurred after an emergency portacaval shunt in a patient who massively rebled after randomization but before elective surgery could be performed. The single early sclerotherapy fatality was secondary to uncontrolled hemorrhage after the first sclerosis session.

Surviving shunt and sclerotherapy patients have been followed up for a mean of 24.4 ± 3.3 and 25.2 ± 3.3 months, respectively. Figure 1 shows Kaplan-Meier survival plots for the two groups as of March 1, 1987. These two curves as well as 2-year survival rates for shunt (65%) and sclerotherapy (61%) groups are not significantly different. Two of four patients in whom sclerotherapy failed who had surgery (splenectomy plus devascularization = 1, interposition mesocaval shunt = 1, end-to-side portacaval shunt = 2) for uncontrolled hemorrhage are still surviving.

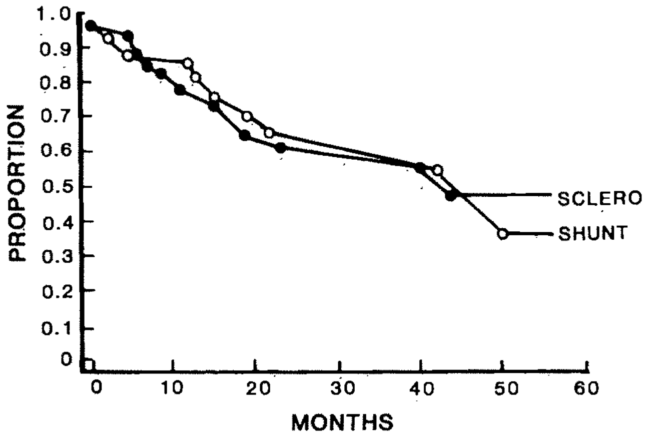

FIG. 1. Kaplan-Meier survival curves for shunt surgery (O) and endoscopic sclerotherapy (●). The curves are not different at any time interval.

The predominant cause of death was different in the sclerotherapy and shunt groups. Eight of the 12 sclerotherapy deaths (67%) resulted from recurrent hemorrhage. Of these eight patients, one died of continuing hemorrhage 5 days after randomization, two died after surgery (2 weeks after mesocaval shunt and 2 years after splenectomy plus devascularization), three died in outlying hospitals more than 300 miles from the tertiary care center, and two died of hepatic failure induced by hemorrhage and were unacceptable candidates for surgery. Six of the eight patients had had endoscopy within the previous month, five bled from gastric varices or portal hypertensive gastropathy rather than from the esophagus, and only one patient was noncompliant. The remaining four sclerotherapy fatalities were secondary to hepatic failure (N = 1), esophageal carcinoma (N = 1), and pneumonia (N = 2). The mean pretherapy Child's score of nonsurviving patients (6.6 ± 0.6) was identical to that of survivors (6.6 ± 0.4).

Six of the 10 shunt deaths (60%) were secondary to hepatic failure. Four of these individuals had resumed heavy alcohol consumption, and the other two had nonalcoholic cirrhosis. Two shunt patients died of recurrent variceal hemorrhage (one after thrombosis of DSRS and one after emergency portacaval shunt for recurrent hemorrhage before elective surgery). The remaining shunt deaths were due to myocardial infarction (N = 1) and ruptured abdominal aortic aneurysm (N = 1). Six of 23 (26%) patients who received the DSRS and three of four (75%) patients with nonselective shunts have died. The mean preoperative Child's score for nonsurviving shunt patients (7.2 ± 0.6) was not significantly higher than for survivors (6.0 ± 0.5).

Failure of Therapy

Failure of therapy (death or change in therapy) curves for the two groups are shown in Figure 2. At no point are the two curves significantly different. Fourteen patients (12 deaths and two survivors of shunt surgery) failed sclerotherapy. Two sclerotherapy patients had surgery and subsequently died. Failure was caused by recurrent hemorrhage in 10 patients (71%). These patients had 8.4

± 1.2 sclerosis sessions and experienced 3.3 ± 0.6 recurrent hemorrhages requiring 5.8 ± 0.7 units of blood per episode. No pretherapy variables significantly separated sclerotherapy successes from failures.

All 10 therapy failures in the shunt group were due to death rather than change of therapy. The single patient who was treated with chronic sclerotherapy after DSRS thrombosis eventually died of recurrent hemorrhage. Early postoperative shunt thrombosis developed in two patients (one DSRS and one interposition portacaval shunt), but both patients were successfully reshunted (one end-to-side portacaval shunt and one interposition portacaval shunt). The overall shunt thrombosis rate was 11%. The only preoperative variable that significantly separated success (survival) from failure (death) in the shunt group was GEC (survivors = 298 ± 26 mg/min, nonsurvivors = 217 ± 20 mg/min; p = 0.05).

Recurrent Hemorrhage

The percentage of patients who rebled, number of rebleeding episodes, and number of units of blood transfusion were all significantly higher in the sclerotherapy group (Table 3). Of the 17 sclerotherapy patients who rebled, 10 (59%) were therapy failures and are discussed above. The remaining seven patients have had either one or two recurrent hemorrhages that have been successfully controlled with sclerotherapy. Most hemorrhages have been documented to be from varices or hypertensive gastropathy by endoscopy; no other lesions have been identified. Pretherapy prothrombin time and partial thromboplastin time were significantly longer (p = 0.05 and p = 0.004, respectively) in sclerotherapy patients who rebled. All other pretherapy variables were similar in patients with and without recurrent hemorrhage.

Three of the five shunt patients who rebled had shunt thrombosis. The remaining two patients had mild recurrent hemorrhage in the early postoperative interval and had patent DSRS by angiography.

Hepatic Function

Neither the quantitative hepatic function tests nor the conventional measures of liver function were significantly different between groups at 1 or 3 years. Likewise, serial GEC, ICG, and Child's score determinations showed no significant changes at 1 year in either group (Table 4). Too few serial measurements have been completed at 3 years for statistical analysis.

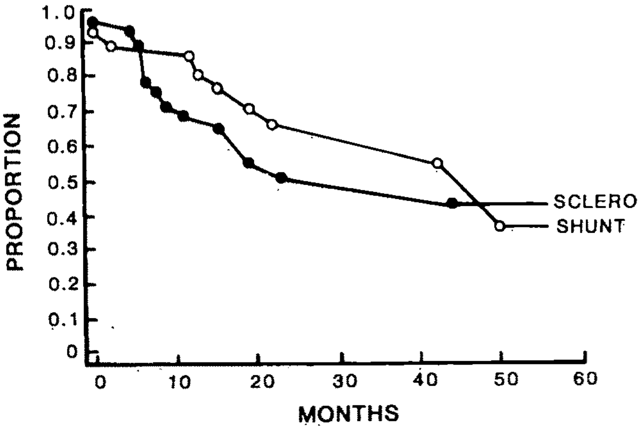

FIG. 2. Kaplan-Meier plots of therapy failure for shunt surgery (O) and endoscopic sclerotherapy (●). The curves are not significantly different at any time interval.

Hepatic Hemodynamic Data

Early postoperative angiography showed preservation of hepatic portal perfusion after 20 of 23 DSRSs and after none of the nonselective shunts. Likewise, corrected sinusoidal pressure (CSP) was maintained in the early postoperative interval after DSRS (preoperative = 15.7 ± 0.9 mmHg, postoperative = 18.0 ± 1.6 mmHg). Analysis of unpaired data at 1 and 3 years showed a significant difference between groups in only CSP at 1 year (shunt = 9.9 ± 1.1 mmHg, sclerotherapy = 16.4 ± 1.8 mmHg; p = 0.01). Serial measurements of EHBF, PPG, and CSP showed a significant change in PPG and CSP in the shunt group at 1 year (Table 5). Four of seven patients who had DSRS and one of eight patients who had sclerotherapy had a worse PPG at 1 year than before therapy (Fig. 3). Since all nonselective shunt patients had lost portal flow immediately after surgery, late postoperative angiograms were not done in these individuals. When nonselective shunt patients surviving at 1 year (shunt group = 3, sclerotherapy group = 2) are considered with DSRS and sclerotherapy patients who had late postoperative angiography, five of 10 shunt patients (50%) and seven of 10 sclerotherapy patients (70%) had evidence of continuing hepatic portal perfusion at 1 year. Two of three angiograms performed at 3 years after DSRS showed hepatopetal portal flow; the single 3-year study in the sclerotherapy group also revealed preservation of portal flow.

Psychoneurologic Function

Four (16%) at-risk shunt patients and two (7%) sclerotherapy patients had at least one episode of spon-

taneous encephalopathy during the follow-up interval (Table 6). This complication required hospitalization on four occasions (two patients) in the shunt group and a single hospitalization in the sclerotherapy group. An additional four (14%) sclerotherapy patients had encephalopathy in association with recurrent hemorrhage. Nine shunt (43%) and six sclerotherapy (26%) patients had an abnormal EEG on at least one occasion after initiation of therapy. Overall, there were no differences between groups with respect to clinical, EEG, or psychometric manifestations of post-therapy encephalopathy (Table 6).

Medical Costs

Initial medical costs were significantly higher for shunt patients ($22,473 ± 3521, N = 14) than for sclerotherapy patients ($10,410 ± 1893, N = 14) ($p = 0.007$). However, total medical costs were similar in the two groups (shunt = $34,474 ± 5499; sclerotherapy = $37,648 ± 6392) during a mean follow-up interval of 20 ± 5 and 24 ± 6 months for shunt and sclerotherapy patients, respectively. The higher follow-up costs in the sclerotherapy group were due to the need for serial endoscopies and more frequent hospitalizations (shunt = 16, sclerotherapy = 34) in that group.

Discussion

The major finding of this study is that elective shunt surgery and chronic endoscopic sclerotherapy provide similar long-term survival rates and quality of life for cirrhotic patients who bleed from esophageal varices. The most common causes of death in shunt and sclerotherapy patients were hepatic failure and recurrent hemorrhage, respectively. Despite a comprehensive pretherapy evaluation that included multiple hemodynamic variables and quantitative measures of hepatic function, no test accurately predicted survival in the sclerotherapy group. Although functional hepatic reserve, usually assessed by Child's class, has been a useful prognosticator in some sclerotherapy series,[7,20] pretherapy Child's score was identical in patients who survived and in those who died after endoscopic sclerosis in the current investigation. In contrast, quantitative hepatic function as estimated by GEC predicted survival after shunt surgery. After a 2-year minimum follow-up, five of seven shunt patients with a preoperative GEC less than 250 mg/min have died. Only one patient with a GEC greater than 250 mg/min has died. Although preoperative Child's score was higher (worse hepatic function) in nonsurvivors than in survivors in the shunt group, this difference did not reach statistical significance. These results suggest that chronic sclerotherapy may be preferable to shunt surgery for patients with marginal hepatic reserve.

The 57% of sclerotherapy patients in whom recurrent hemorrhage developed is in the range reported by others.[7,8,20] Ten of the 17 patients with recurrent bleeding had catastrophic hemorrhage, which resulted in death in eight patients. Four of the ten patients had surgery, and two are currently alive. Thus, only two sclerotherapy failures have been salvaged by surgery. Several factors account for this low salvage rate. Recurrent hemorrhage was severe in all of these patients and the location of bleeding in the stomach rather than the esophagus in several individuals prevented temporary

control by balloon tamponade or endoscopic sclerotherapy. In addition, three patients who failed sclerotherapy lived more than 300 miles from the tertiary hospital and bled to death before they could be transported. The three patients who died in our hospitals without surgical intervention had severe hepatic functional decompensation and coma develop secondary to recurrent hemorrhage. These patients were believed to be nonsalvageable, therefore surgery was not performed.

Although a majority of recurrent bleeding episodes (69%) occurred during the first year before variceal eradication was complete in many patients, five of eight fatal hemorrhages occurred in years 2–4, and three of these patients had had prior eradication of esophageal varices. Others[7,8] have also reported recurrent hemorrhage after variceal eradication, confirming the necessity of serial endoscopies in such patients. However, even careful follow-up is no guarantee against fatal hemorrhage as six of the eight patients who bled to death in this series had had endoscopy within 1 month of the fatal episode. Four of these patients had received variceal injections during endoscopy. Because of the frequency and severity of recurrent hemorrhage, pretherapy variables were analyzed to determine if any were predictors of this complication. Only prothrombin time and partial thromboplastin time separated the subgroup that rebled from the subgroup that did not, but the large overlap between subgroups limited the usefulness of these tests for prediction of recurrent hemorrhage.

In addition to prevention of variceal hemorrhage, two objectives of the DSRS are preservation of hepatic portal perfusion and maintenance of portal hypertension. Portal blood contains hepatotrophic hormones essential for maintaining liver size and function and unidentified substances believed to cause encephalopathy when they bypass the liver. Splanchnic venous hypertension may inhibit intestinal absorption of these cerebral toxins.[21] One aim of the current investigation was to determine whether portal flow is more rapidly collateralized after selective variceal decompression (DSRS) than occurs in the natural history of cirrhotic portal hypertension (sclerotherapy group). Both portal flow and CSP were well maintained in the early postoperative studies after DSRS. However, PPG was significantly increased (worsened) 1 year after DSRS, but was unchanged in the sclerotherapy group. Others[22,23] have also reported gradual loss of hepatic portal perfusion during the late postoperative interval after the DSRS, especially in patients with alcoholic cirrhosis. CSP, which reflects portal venous pressure in patients with cirrhosis,[24] was also significantly decreased 1 year after DSRS. Thus far, these late postoperative hemodynamic effects of the DSRS have not translated into major alterations in hepatic or psychoneurologic function. Although a higher percentage of shunt patients have developed spontaneous encephalopathy and abnormal EEGs, the differences between groups are not statistically significant. It is possible that differences in these variables as well as in the quantitative tests of hepatic function may become apparent as the interval of follow-up lengthens.

The results of this study differ from the recently published Emory University trial by Warren and coworkers[20] who reported significantly longer survival and better hepatic function in cirrhotic patients treated by sclerotherapy than for those undergoing elective DSRS.

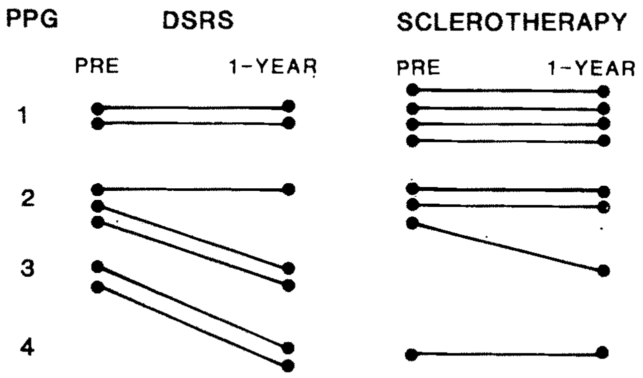

FIG. 3. Angiographic portal perfusion grades (PPG) before and 1 year after DSRS and endoscopic sclerotherapy. The change in PPG is significant after DSRS (p = 0.03) but not after sclerotherapy.

Two-year survival rates for the shunt groups in the two trials are similar (current study, 65%; Emory trial, 59%). In contrast, survival at 2 years after initiation of sclerotherapy in the Emory trial (84%) was greater than for our sclerotherapy group (61%). The major difference between the two investigations is the greater success of the Emory group in salvaging sclerotherapy failures by shunt surgery. At the time of their report, 11 sclerotherapy patients (31%) had undergone surgery and eight (22%) were still surviving. Only four patients (13%) in our sclerotherapy group received surgery and two (7%) are currently alive. Our inability to salvage more sclerotherapy failures was due to generally catastrophic recurrent hemorrhage, often during the first episode, which led to rapid deterioration of hepatic function.

Although the designs of these two trials are similar, several subtle differences may account for the conflicting results observed. First, the patient populations are different. The current investigation contains higher percentages of alcoholic cirrhotics (86% *vs.* 61%) and Veterans Administration Hospital patients (51% *vs.* 0). Although Warren and co-workers[20] reported a higher percentage of Child's C patients than in the current study (44% *vs.* 33%), the methods of classifying patients differ. Analysis of pretherapy data from the two investigations shows higher mean bilirubin and lower mean albumin and GEC in our trial, suggesting inclusion of patients with more advanced hepatic dysfunction. Only patients acceptable for the DSRS (hepatopetal portal flow and manageable ascites) were entered into the Emory trial. We accepted all patients who could undergo any type of shunt, although only three patients had spontaneous reversal of portal flow on pretherapy angiography and 85% of patients in the shunt group received the DSRS. Finally, in the current study, a significant percentage of patients (including three sclerotherapy failures) had to travel over 300 miles to return to the tertiary hospital because of the relatively sparse population and large geographic area of the Intermountain West and Plains compared with the Southeast. Thus, shunt surgery may be preferable to chronic sclerotherapy for patients living in such remote areas. Although it cannot be determined whether these factors account for the differences in results, they should be considered when interpreting the data from the two trials.

The only other study[25] that has compared shunt surgery and sclerotherapy comprised exclusively Child's C cirrhotic patients who were receiving emergency therapy for acutely bleeding varices. Therefore, it is not directly comparable to either the current investigation or the Emory trial.[20] This report by Cello and co-workers[25] showed similar short- and long-term survival rates for portacaval shunt and sclerotherapy patients. As in the current trial, recurrent hemorrhage was significantly more common in the sclerotherapy group and total medical costs were similar for both therapies, even though shunt surgery was significantly more expensive during the initial hospitalization.

In summary, at a mean follow-up interval of 2 years, this randomized trial has shown similar survival rates, levels of hepatic and neuropsychologic function, and total medical costs after shunt surgery (85% DSRS) and chronic endoscopic sclerotherapy. Hepatic portal perfusion and portal pressure were better maintained after sclerotherapy, but this hemodynamic advantage has not yet resulted in a differential in hepatic function between groups. Recurrent hemorrhage was more frequent after sclerotherapy (57%) and was the most common cause of therapy failure. Because of the severity of recurrent bleeding and geographic distribution of patients, only two of 10 sclerotherapy failures have been salvaged by surgery. Although none of the pretherapy variables predicted failure of sclerotherapy, preoperative GEC was significantly higher in shunt survivors than in nonsurvivors, suggesting that patients with limited hepatic functional reserve might be better served by sclerotherapy than by shunt.

Acknowledgments

The authors thank Fred Ullrich and Dr. Kashinath Patil for statistical analysis and Ms. Angella Pieper for preparation of the manuscript.

Discussion

DR. LOUIS R. M. DEL GUERCIO (New York, New York): I am filled with admiration for the authors' ability to perform this difficult piece of work in such a fine fashion. Those who deal with these types of patients know how difficult it is to maintain such controls.

I rise simply to speak about the patients who fail sclerotherapy. Sclerotherapy can be compared with the little girl with the curl in the middle of her forehead. When it's good, it's very, very good, and when it's bad, it's terrible. The question is what to do with the sclerotherapy failures.

The authors point out that they could salvage only 20% of these sclerotherapy failures, that is, those who continue to bleed despite attempts at sclerotherapy.

(Slide) We have been very concerned with this because at our institution, the Westchester County Medical Center, most bleeding cirrhotics who are referred to us are sclerotherapy failures.

What we do is a combination of splenic artery embolization through the standard Seldinger approach, putting Gianturco coils in the splenic artery to reduce the splenic contribution to portal flow and to reduce the degree of secondary hypersplenism with improvement in platelet counts.

The second part of the procedure is performed through a minilaparotomy in the x-ray suite under local anesthesia. We cannulate a branch of the mesenteric vein, go up into the portal system, and internally sclerose the coronary collaterals to the varices with absolute alcohol and use Gianturco coils to plug off the collaterals. In other words, this is a nonoperative Sugiura operation.

(Slide) In 36 consecutive patients (no one excluded) who were sclerotherapy failures, all of the Class B patients survived for at least 1 year. The red shows the survival of the Class C cirrhotics where 60% survived for at least 1 year, and the combination of Bs and Cs had an even better survival.

This is a satisfactory alternative to shunt surgery and can be done expeditiously in the x-ray department.

My question to the authors is: what are their plans in terms of better management of the sclerotherapy failures?

DR. JOHN PHILIP SANDBLOM (Sweden): I first express great happiness in having survived to be able to attend once more the summit of the surgical year, the meeting of the American Surgical Association! This gives me the opportunity to discuss one of the great interests in my surgical life with this excellent presentation of comparing shunt and sclerotherapy in portal hypertension.

My experience is long; it started 40 years ago and we once had one of the largest series of shunt operations in the world. I have always advocated the shunts for portal hypertension, although during recent years less successfully, as these have been in less favor. I am therefore very pleased to have this judged objectively with a prospective study, to see that the two methods are equal in many respects, and that we shall be able to continue doing the shunts with good prospects.

There are two more benefits from normalization of the portal pressure. Firstly, it corrects the stasis in the splanchnic tissues, for example in the gastric mucosa where erosive gastritis often ensues. Secondly, it relieves the patients of the great danger of severe hemorrhage after abdominal trauma or abdominal operations. I have once seen a patient with portal hypertension die of hemorrhage during a simple cholecystectomy.

In our series we had several cases of biliary cirrhosis due to ascending cholangitis from biliodigestive shunts. These patients often need reoperations for correction of anastomotic strictures.

In the first case we had great difficulties with hemorrhage. In the three remaining cases, we performed the operation in two stages: first the shunt operation and then when the portal pressure had been reduced to normal, with hemostasis.

I ask the authors if they have any experience with the advantage of normalizing the portal pressure in these cases.

DR. J. MICHAEL HENDERSON (Atlanta, Georgia): I congratulate Dr. Rikkers for putting surgical decompression and endoscopic sclerosis of varices to the true test of a prospective randomized clinical trial. In a similar trial at Emory our data look different.

My main area of discussion will focus on failures of sclerotherapy. In our study, 16 of 37 patients randomized to sclerotherapy either died or failed that therapy: four patients had their bleeding controlled, but have died of hepatic failure, one patient in this group has died of bleeding, which is in marked contrast to Dr. Rikkers' study, the other 11 patients had recurrent bleeding severe enough to be considered sclerotherapy failures and crossed over to shunt surgery. There was no operative mortality in these 11 cross-over patients, but four have subsequently died of hepatic failure at 3–47 months after cross-over.

The second major difference in the results of our two studies lies in the effect of therapy on liver function. At randomization, the severity of liver disease appears similar in the two studies. Our study, in contrast to Dr. Rikkers', showed significant improvement in hepatocyte function in the sclerotherapy group over time. Improvement in the galactose elimination capacity occurred predominantly in alcoholic cirrhosis patients, in whom frequent return for sclerotherapy may have been an added incentive to stop drinking.

These two factors, the ability to surgically salvage sclerotherapy rebleeding failures, and improved hepatic function in the sclerotherapy group, combine in our study to give significantly improved survival to that group. The survival curve of our shunt group is similar to Dr. Rikkers' survival curves for both his groups, but at all time points the survival curve of our sclerotherapy group is significantly ($p < 0.03$) better than our shunt group. At a median 3.5-year follow-up, the sclerosis group, with surgical salvage of 30% of the patients, has a significantly better outcome. Our study supports an approach of initial sclerotherapy for all patients, which allows time to define their liver disease and its course. Failures from rebleeding or progressive liver disease can then be rationally referred for further therapy by shunt surgery or transplantation as appropriate.

I ask two questions: first, sclerotherapy is a viable treatment for some patients. Has it altered how you advise your patients outside the confines of your randomized study? Second, what are the key factors in sclerotherapy rebleeding? Is it access to the therapy? Is it technique? Or is it patient population?

DR. IWATSUKI (Pittsburgh, Pennsylvania): I also compliment Dr. Rikkers and his colleagues on their well-designed clinical study. We have been interested for some time in treating variceal bleeding of far-advanced cirrhosis by radical portal decompression through a normal liver graft, or to put it more plainly, with orthotopic liver transplantation.

I present our preliminary results of liver transplantation for bleeding esophageal varices in far-advanced cirrhosis.

(Slide) Among 500 consecutive patients who received liver transplantation under cyclosporine and steroid therapy, more than 1.5 years ago, 136 patients had had definite history of bleeding from esophageal varices. All 136 patients were classified in Child's C or an even worse category.

The 1-year actual survival rate after transplantation was 80% and the 3- and the 5-year actuarial survival rates were 73% and 70%, respectively.

(Slide) The survival rates of patients with far-advanced cirrhosis or Child's class C were vastly different after liver transplantation than those after Dr. Warren's selective shunt, sclerotherapy, Sugiura-type nonshunt procedures, or nonselective portacaval shunt.

In this context Dr. Rikkers' paper is unusually important. He has shown that survival with conservative sclerotherapy is the same as with the best of the shunting procedures.

If this is true, and I believe it is, almost all such shunt operations that greatly complicate the next and the final step of transplantation are going to be abandoned except under the most unusual circumstances.

I ask Dr. Rikkers one question. What is your choice of treatment for bleeding varices on the patients with far-advanced Child's Class C cirrhosis at your institution, now that you have liver transplantation capabilities in Omaha?

DR. MARSHALL J. ORLOFF (San Diego, California): I rise to make three observations about this interesting study by Dr. Rikkers and his colleagues and to briefly describe our recent results that differ substantially from those he has presented.

Firstly, the study that we have just heard involved highly selected patients subjected to elective treatment. Therefore, it dealt with only a portion of the bleeding cirrhotic population, and the conclusions do not apply to all patients who come to the emergency room with bleeding varices.

Secondly, 19% of the patients who had elective shunt rebled, which I believe is quite high. Whenever a shunted patient rebleeds, it represents a failure of the operation.

Thirdly, I must confess to a bit of disappointment in the 2-year survival rate of 65% for elective shunt in selected patients.

(Slide) In 1983, our gastroenterology division performed a prospective evaluation of endoscopic sclerotherapy in unselected cirrhotic patients with bleeding varices. Each patient who entered the medical service for 3 years, all comers included, had emergency endoscopic sclerotherapy and then repetitive long-term sclerotherapy (as many as 17 sessions with an average similar to that of Dr. Rikkers' group of 7 sessions per patient).

The study involved 53 consecutive cirrhotics. Eighty-nine per cent rebled from varices after their final sclerotherapy session. A mean of 16.3 units of blood transfusion was required during the initial hospitalization.

Eleven patients ultimately had a portocaval shunt because of uncontrollable bleeding, and I might say that they made up many of the 2-year survivors.

(Slide) Seventy per cent of the patients survived to leave the hospital after the initial bleeding episode, but almost all of them were soon readmitted because of rebleeding.

As of 1986, 33% of these unselected patients were alive and the 2-year survival rate was only 17%.

The differences are striking when the results of endoscopic sclerotherapy at our institution are compared with our results of the emergency direct portocaval shunt done within 8 hours of admission in 84 unselected patients from 1977–1982.

Rebleeding occurred in 2% of the emergency shunt patients *versus* 89% of the sclerotherapy patients.

The emergency shunt patients required 0.5 units less of transfused blood than the sclerotherapy patients, and 2-year survival was almost 5 times greater in the emergency shunt group than in the sclerotherapy group.

(Slide) At the AGA meeting last year, we reported the results of a soon to be published prospective, randomized comparison of emergency portocaval shunt and emergency medical therapy followed by elective shunt in unselected patients. Emergency shunt resulted in significantly greater early and long-term survival than emergency medical therapy followed by elective shunt. (Slide) The higher survival rate with emergency shunt was particularly striking in patients with Child's group B, 100% compared with 33%, and Group C, 64% compared with 14%.

This slide compares the 5-year survival curves obtained in our various studies in unselected patients. The survival rates in the two emergency shunt groups, randomized and unrandomized, were similar and were much greater than the survival rate in the randomized medically treated patients followed by elective shunt.

I must point out that the 2-year survival rate of 79% after emergency shunt in unselected patients is greater than the 65% reported by Dr. Rikkers after elective shunt in selected patients.

DR. RAPHAEL S. CHUNG (Syracuse, New York): Unlike shunt surgery, the failure of sclerotherapy is not well known. Failure of a shunt is documented by occlusion, but not many people, especially those who are not endoscopists, know what is the exact cause for recurrent bleeding after sclerotherapy.

One of the puzzling conditions to treat is recurrent bleeding after deep ulcerations in the musculature after sclerotherapy, which is a complication of overzealous treatment because the collaterals in the muscles are eroded and being hypertensive, they tend to bleed persistently.

I ask Dr. Rikkers if any of the patients who had recurrent bleeding from sclerotherapy were bleeding from deep ulcerations and also how many patients in the series developed esophageal strictures? Both of these serve as a rough indication of the quality of the technique of sclerotherapy.

DR. LAYTON RIKKERS (Closing discussion): I thank the discussants for their questions and comments.

Dr. Del Guercio had better results than we have had in salvaging sclerotherapy failures. Only 30% of our sclerotherapy failures were successfully salvaged by surgery and one of these patients died 2 years later. A major cause of the low salvage rate of sclerotherapy failures in our study is the wide geographic distribution of the patients. Several patients died in outlying hospitals and others had advanced hepatic and neuropsychological dysfunction develop by the time of transfer and were no longer salvageable by surgery. These results suggest that shunt surgery may be preferable for patients living in remote areas.

Dr. Sandblom, I do not have experience with portal decompressive procedures before complex biliary surgery in patients with portal hypertension.

Dr. Henderson, our trial and the Emory trial are similar, but there are several important differences that may account for the variance in results. First, the Emory trial compared only the distal splenorenal shunt with sclerotherapy. Therefore, patients with contraindications to the distal shunt, *e.g.*, medically intractable ascites, were presumably excluded. Since nonselective shunts were included in the surgical arm of our study, such patients could be entered. Second, our trial contained a higher percentage of alcoholic cirrhotics and also included VA patients. In addition, we accepted patients within a geographic radius of 500 miles. The Emory trial excluded patients who lived more than 200 miles from Emory University Hospital. The potential importance of geographic distribution has been alluded to already. Finally, there are many ways of categorizing patients by Child's classification. Although the authors of the Emory trial report that 44% of patients were Child's class C compared with 33% of C patients in our trial, a direct comparison of data from the two trials shows that both serum albumin and galactose elimination capacity were significantly lower in our patients. Therefore, it appears that our trial consisted of possibly less compliant patients with more advanced liver disease who lived within a larger geographic area than the patients in the Emory study. It is likely that these factors account for the poorer survival of sclerotherapy patients in our trial.

Dr. Iwatsuki presented impressive results following liver transplantation for variceal hemorrhage. During the past 1.5 years, we have done 90 liver transplants at the University of Nebraska. We also prefer liver transplantation to portal decompression or sclerotherapy for Child's C patients with nonalcoholic cirrhosis who are in the appropriate age range. Unfortunately, few alcoholic cirrhotics are liver transplantation candidates and, therefore, continue to be available for entry into our trial.

Dr. Orloff, our objective was to look at the elective rather than the emergency management of patients with variceal hemorrhage. We have found that a combination of vasopressin, balloon tamponade, and acute sclerotherapy controls hemorrhage in greater than 85% of acutely bleeding patients. Emergency surgery is considered only when these measures fail.

The 19% rebleeding rate in the shunt group includes three patients with thrombosis, two of whom were successfully reshunted, and two patients with patent distal splenorenal shunts who had minor bleeding episodes confined to the early postoperative interval.

I admire Dr. Orloff's salvage rate in his emergency shunt series. However, I believe it is fair to say that no one else has approached his results with emergency shunts.

Dr. Chung, our sclerotherapy failures did not bleed from esophageal ulcers. Rather, they bled from the stomach either from gastric varices or from portal hypertensive gastropathy, which we find to be major consequences of sclerotherapy. The only notable complication of sclerotherapy was esophageal stricture, which developed in three patients. All of these strictures were successfully dilated without surgical intervention.

Evolving Strategies for the Repair of Complex Renovascular Lesions

K. CRAIG KENT, M.D., OSCAR SALVATIERRA, M.D., LINDA M. REILLY, M.D., WILLIAM K. EHRENFELD, M.D.,
JERRY GOLDSTONE, M.D., and RONALD J. STONEY, M.D.

From the Department of Surgery, University of California, San Francisco, California

Fifty-five patients with 59 complex renovascular lesions required two or more branch artery anastomoses during aortorenal grafting. Forty-five reconstructions involving 112 branches were facilitated using hypothermic *ex vivo* perfusion preservation, whereas 14 involving 28 branches were repaired *in situ*. *Ex vivo* repair was used whenever the kidney was considered unreconstructable by *in situ* techniques. Fibromuscular dysplasia predominated and the branched internal iliac artery was used for renal artery substitution. There were no deaths and only one kidney (*ex vivo*) was lost. Branch vessel occlusion occurred in two of 140 anastomoses (1.4%). Ninety-eight per cent (51/52) of the heparinized patients had cure or improvement at mean follow-up of 5 years. No late graft dysfunction occurred in postoperative angiographic follow-up. The branched internal iliac artery is uniquely suited and remains the preference of the authors for the replacement of the diseased renal artery and its branches. The *in situ* repair is ideally suited for lesions limited to the renal artery bifurcation. *Ex vivo* repair is reserved for complex or reoperative distal arterial lesions. Unique characteristics in the group include: bilateral lesions (25%), solitary kidney (22%), reoperative lesions (16%), children (9%), and coexisting significant aortic disease (7%). *In situ* and *ex vivo* repair meet all the challenges of complex renovascular disease. The strategies outlined will achieve outstanding long-term total and segmental renal salvage in the treatment of hypertension or aneurysmal disease. When *ex vivo* repair is required, it can be accomplished with only one additional simple maneuver, the reanastomosis of the renal vein.

THE COMBINATION OF the arterial autograft, temporary hypothermic kidney perfusion, and microvascular branch renal artery repair[1,2] was the basis for the original report on *ex vivo* renal artery reconstruction more than a decade ago.[3] Ongoing experience salvaging kidneys threatened by complex lesions of the distal renal vasculature has convinced us of the validity of this operative approach and better defined its application.[2,4]

This report analyses the results of 55 patients requiring extensive surgical reconstruction of a wide spectrum of challenging lesions of the distal renal artery and its branches. Not all distal renal artery lesions have required *ex vivo* repair, and we now selectively perform *in situ* renal artery replacement when lesions are confined to the primary renal bifurcation. A review of our experience has evolved a strategy that allows both anatomic and functional reconstruction of a normal renal arterial system with consistent kidney salvage and amelioration of hypertension.

Clinical Material

Among 135 patients who had iliac artery autograft reconstruction for significant renovascular lesions between 1964 and 1986, 55 patients (40%) required multiple branch arterial repair because of the distal extent of their lesions and represent the case material for this study (Table 1). There were 50 females (92%) and five males (8%) with a mean age of 40.1 years (range: 12–68 years).

In 52 procedures (12 *in situ*, 40 *ex vivo*) (89%), the indication for renal revascularization was diastolic hypertension, with a mean duration of 6 years. Six patients had renal artery aneurysms (2 *in situ*, 4 *ex vivo*) (10%). In the remaining patient, a kidney harvested for transplant was discovered unexpectedly to have fibromuscular dysplasia. The considerable majority of patients (85%) had normal serum creatinine levels before operation. However, two patients who had *in situ* procedures and six patients who had *ex vivo* procedures had evi-

Submitted for publication: April 24, 1987.

dence of impaired renal function before surgery (serum creatinine level ≥ 1.3 mg/dL).

Fourteen reconstructions (14 patients, 17 kidneys) were performed *in situ,* whereas 45 renal artery repairs (41 patients, 45 kidneys) required the *ex vivo* technique. All *in situ* repairs involved two renal artery branches. *Ex vivo* repairs involved two branches in 24 patients, three branches in 11 patients, and four branches in seven patients. Three *ex vivo* repairs in reoperative cases involved only the main renal artery or one branch. The mean number of branches repaired in *ex vivo* procedures was 2.5.

Twenty-six patients (47%) had total renal parenchymal revascularization. Solitary kidneys were revascularized in 12 patients (3 *in situ,* 9 *ex vivo*) (22%). Bilateral renal reconstruction was performed in 14 patients (25%) (staged in 5 patients and simultaneous in 9 patients). Three patients had bilateral *in situ* repairs, two had bilateral *ex vivo* repairs, and two had one *in situ* and one *ex vivo* repair each. The remaining seven patients had *ex vivo* repair on one side and contralateral *nonbranched in situ* repair. These seven nonbranched repairs are not discussed in this report. Nine cases were reoperative (1 *in situ,* 8 *ex vivo*) and five were performed in children (2 *in situ,* 3 *ex vivo*). Only four patients required concomitant aortic reconstruction.

Although selective traditional screening tests were used, the intravenous pyelogram (21 of 28 positive, 75%) and renal vein renin determinations (20 of 23 positive, 87%) were helpful but not absolute indicators of renovascular hypertension. Aortography, supplemented by selective renal arteriography with magnification and multiple views, reliably defined these distal patterns of branch vessel disease.

TABLE 1. *Clinical Material*

Technique	No. of Patients	Kidneys	Branches	Indication	
				Hypertension	Aneurysm
In situ	14	17	28	12	2
Ex vivo	41	45	112	40	4
Total	55	62	140	52	6

Technique

A midline abdominal incision was routinely used for both *in situ* and *ex vivo* repair. Retroperitoneal exposure of the aorta and renal arteries was accomplished through the retroperitoneal midline for *in situ* bifurcation repairs. *Ex vivo* repairs were facilitated by medial reflection of the ascending or descending colon. This gave full exposure of the kidney, the course of the ureter, and the ipsilateral iliac arterial system. Circumferential mobilization of the pararenal aorta, involved renal artery, and accompanying vein were accomplished. The hypogastric artery was mobilized from its origin to its second or third order branches depending on the type of renal replacement required, but was not harvested until the time for grafting. For *ex vivo* reconstruction, after opening of Gerota's fascia, the kidney was fully mobilized, together with the ureter and its accompanying vasculature, down to the level of the pelvic brim. This allowed the kidney to be conveniently perfused on a lower abdominal platform without dividing the ureter.

In Situ *Reconstruction*

A previous report[5] described this technique, which requires a short interval of total aortic occlusion. The segment of aorta chosen for the origin of the autograft is immediately inferior to the origin of the diseased renal artery. Total rather than partial aortic occlusion facilitates placing the circular aortotomy for the proximal anastomosis in a posterolateral position. This aortotomy should match the diameter of the proximal end of the hypogastric artery. The anastomosis is performed with interrupted sutures of fine silk. The superior renal artery branch is ligated at the distal extent of the disease, and the branch vessel beyond that point controlled with a fine vascular clamp. This branch is then transected, gently dilated, and anastomosed to the superior autograft branch with interrupted fine sutures. Flow is restored to the renal parenchyma supplied by this branch through the autograft while the inferior renal artery branch is transposed to an autograft branch in an identical manner. The excluded diseased renal artery is then resected for pathologic examination. The mean renal ischemia time for *in situ* repair was 42.6 minutes (range: 16–102 minutes).

Ex Vivo *Reconstruction*

After extensive mobilization of the renal vessels from their junction with the vena cava and aorta to the renal hilus, the kidney and ureter are freed. The renal artery and vein are controlled with vascular clamps and then transected, and the kidney is positioned on the lower anterior abdominal wall. A tourniquet is placed securely around the ureter to prevent collateral flow into the kidney during the *ex vivo* perfusion. Ringer's lactate solution at 4 C is flushed through the renal artery until the venous effluent is clear. The renal artery is cannulated and then connected to the perfusion manifold of the dissecting platform located on the lower abdominal wall. Hypothermic perfusion is begun and the kidney maintained at about 8–12 C. Thorough dissection of the renal artery branches and vein is possible far into the hilus, to a level distal to visible and palpable disease (Fig. 1). The skeletonized distal renal artery and its branches are now ready for replacement.

The arterial autograft is now harvested, its lumen irrigated with heparinized saline solution, and its configuration studied to match that of the renal arterial tree to be

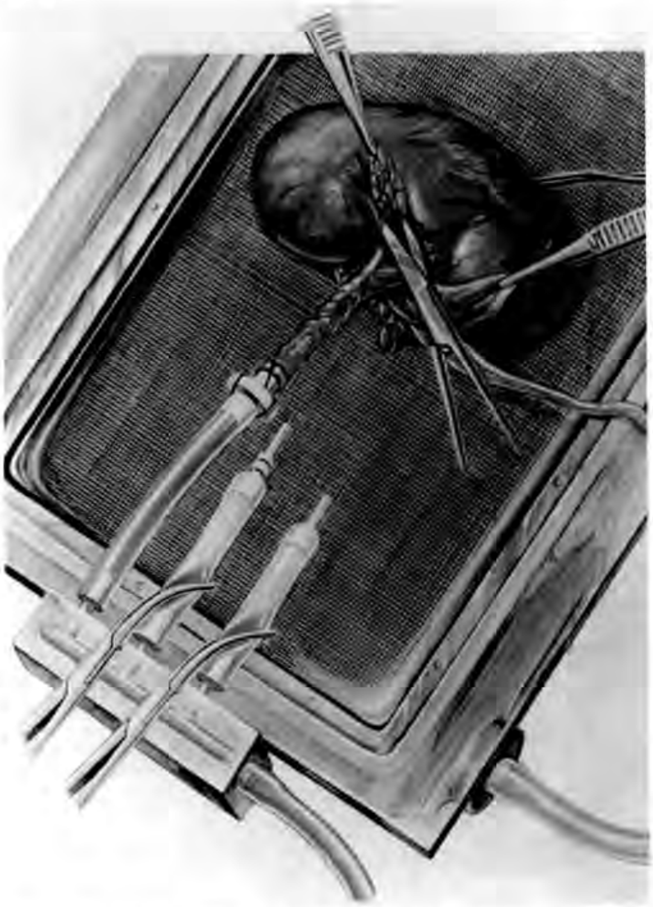

FIG. 1. Extended dissection of renal hilus being performed with hypothermic perfusion through the diseased native renal artery. Note intact ureter and additional cannulae, to which the autograft will be attached.

replaced. Sequential branch anastomosis allows segmental transfer of the circulation from the diseased native renal artery and its branches, under perfusion, to the hypogastric artery substitute, which is connected to another port on the perfusion manifold. Segmental renal ischemia averages 15 minutes for each of the two, three, or four vessels to be anastomosed. The hypothermic perfusion is therefore nearly continuous and maintains a surface temperature of between 8 and 12 C. Interrupted 6-0 or 7-0 Tycron sutures are used for the anastomoses. Vessels under 2 mm in diameter are anastomosed over a metal dilator stent to allow precise end-to-end approximations and to prevent anastomotic narrowing.

The reconstructed renal artery tree is examined for leakage by temporarily elevating the perfusion pressure to the patient's systolic pressure. If identified, these can be easily and precisely repaired. The perfusion pressure is returned to a lower level for an additional 10 minutes to ensure maximum renal hypothermia before reimplantation. The kidney is placed in the renal fossa and the artery is attached first to the posterolateral circular aortotomy, using the technique previously described for *in situ* repair. The renal vein is reattached to the native renal vein (left side) or to an elliptical cavotomy (right side) using continuous suture technique. The venous and arterial clamps are now removed restoring the renal circulation. The mean perfusion time for *ex vivo* repairs was 94.3 minutes (range: 57–160 minutes), whereas the mean warm renal ischemia time was 57.8 minutes (range: 21–91 minutes).

Results

There were no deaths in this patient group. Significant nonrenal morbidity occurred in seven patients (12%), and was major in three (requiring reoperation) and minor in four. Intraoperative (2) and postoperative (2) graft occlusion occurred in four patients (5 kidneys), three in the *in situ* group and one in the *ex vivo* group. The *ex vivo* kidney was lost, whereas all four *in situ* kidneys were salvaged. Postoperative branch occlusion occurred in only two branches, both in kidneys reconstructed using the *ex vivo* technique. No patient required dialysis. Seven patients who had *ex vivo* procedures demonstrated a transient decline in renal function after operation, which had resolved at the time of discharge (Table 2). Three patients who had *in situ* procedures had a similar decline in function, but *did not* recover their preoperative level of function before the time of discharge. Follow-up renal scans revealed no kidney to manifest acute tubular necrosis.

Among the 52 patients who had diastolic hypertension, at discharge all patients were either cured or improved. Late follow-up, obtained at a mean interval of

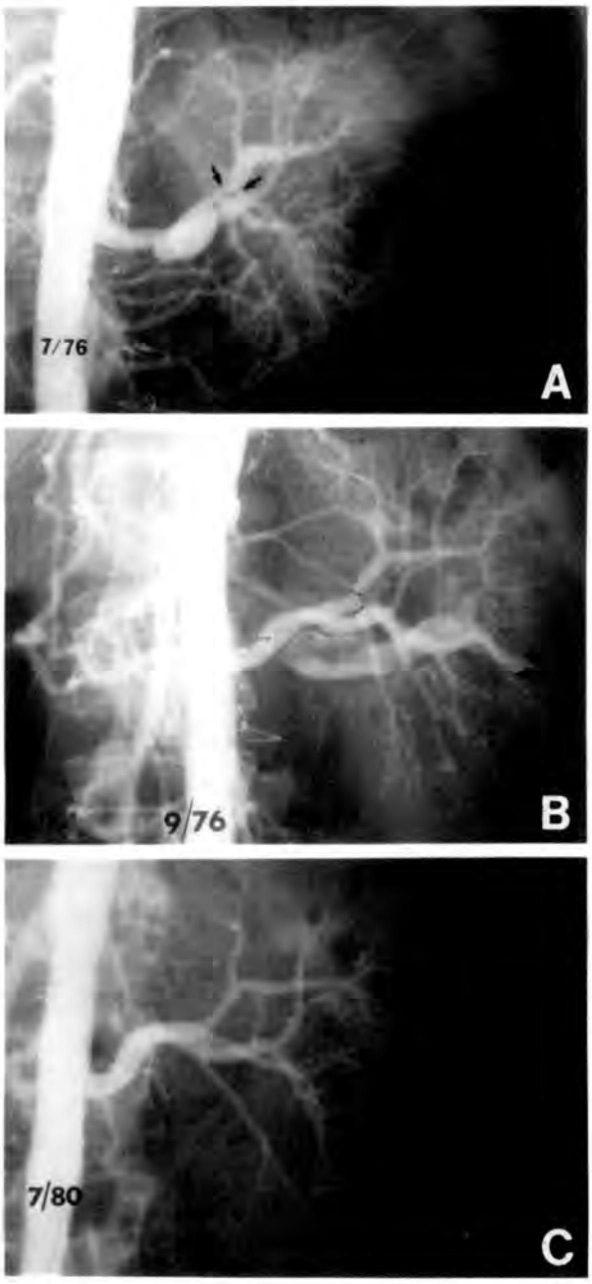
76 months (range: 1–168 months), showed that 51 of 52 patients (98%) remained either cured or improved (Table 2). The one patient who was worse at follow-up was the patient who lost her kidney.

Late arteriographic assessment was performed in 24 patients (44%) at a mean time of 40.6 months after operation (range: 1–122 months). Stable graft configuration was demonstrated in all patients, without graft degeneration or stenosis (Figs. 2 and 3).



FIGS. 2A–C. *A*. Aneurysmal deterioration of a vein patch angioplasty used to incompletely treat extensive fibromuscular dysplasia in a solitary kidney. Note significant disease involving branches distal to the patch (arrows). *B*. Postoperative study after *ex vivo* repair. Arteriovenous fistula is secondary to a percutaneous renal biopsy. *C*. Late follow-up study shows normal-appearing renal architecture.

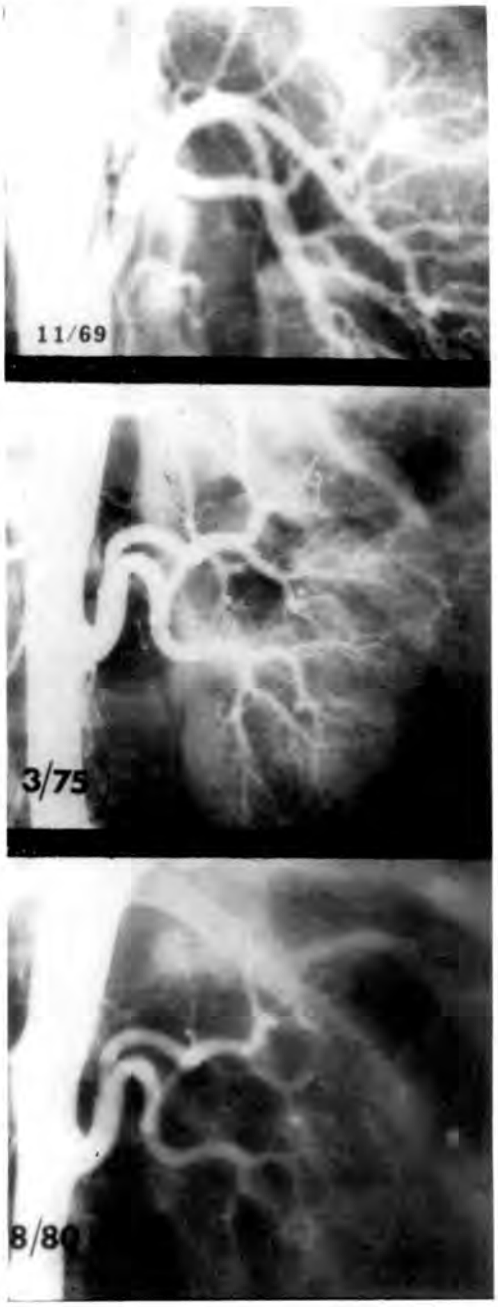


FIG. 3. Serial arteriograms obtained 6 and 11 years after *in situ* branched renal artery. Note preservation of normal renal anatomy.

Indications for *Ex Vivo* Repair

Various factors, alone or in combination, favor *ex vivo* renal artery reconstruction over *in situ* repair. The two basic principles of the successful management of these complex distal lesions are: (1) uncompromised exposure must be provided to get beyond the disease limits, and (2) adequate time must be taken to perform the meticulous repair without unduly risking renal function. Certain circumstances tend to impede either or both of these requirements.

Extent of Disease

Fibromuscular disease, aneurysmal disease, and spontaneous dissection commonly involve the renal arterial tree beyond the primary and even secondary branch points. At each branch point there is a rapid reduction in renal artery size. In addition, in the renal hilus there is a close relationship of arterial, venous, and collecting system structures. Unobstructed exposure is necessary to allow safe performance of the extensive dissection, precise identification of the involved segments, and meticulous arterial repair, which are necessary to construct a normal renal artery. Therefore, only if the lesion is limited in extent and located solely in the primary renal bifurcation, can an *in situ* repair be performed safely (Fig. 4). If primary bifurcation disease is extensive or if multiple renal artery branches are involved, then *ex vivo* reconstruction is necessary (Figs. 4 and 5).

Reoperative Renal Reconstructions

When a primary renal artery reconstruction has failed because of significant residual lesion, degeneration of the repair (Fig. 2A), or progression of previously insignificant distal disease, reoperation is warranted. If the procedure will involve the main renal artery only, this can usually be successfully approached *in situ* (Fig. 6). However, if the repair will require reconstruction of the primary bifurcation or more distal segments of the renal arterial tree, then the *ex vivo* technique is necessary (Figs. 4 and 5). Previously, these circumstances often led to nephrectomy. Currently, the *ex vivo* approach makes renal salvage feasible for these technically difficult and challenging procedures. Among our nine patients who had reoperation, eight had *ex vivo* repair and transient renal dysfunction followed in three cases. Only seven of 49 primary operations were followed by renal function decline, but in three of these cases it was persistent at discharge. Thus it seems that reoperation is associated with a higher risk of renal injury, and the protection offered by *ex vivo* repair with cold perfusion is important in minimizing at least the severity if not the actual incidence of the renal injury.

Solitary Kidney

A solitary kidney affected with distal disease may have anatomy appropriate for the *in situ* technique. However, the *ex vivo* technique offers a higher degree of safety in reducing significant renal parenchymal injury. Not uncommonly a patient with a solitary kidney already has a measurable degree of impaired renal function, as was the case with five of the 12 patients with solitary kidneys in this study. Not surprisingly, then, 50% of patients (6 of 12) with solitary kidneys had some renal function decline after repair, compared with only 9% of patients (4 of 46) with two kidneys, even though nine of these patients had simultaneous bilateral renal revascularization. Among patients who had *ex vivo* procedures and had solitary kidneys, renal function change was transient, whereas among patients who had *in situ* procedures it was persistent at discharge. We conclude that when the patient does not have the luxury of contralateral renal function, there is a significant risk of repair-associated renal injury and the *ex vivo* technique is safer both in terms of immediate and long-term results.

Discussion

The past three decades have seen an evolution of techniques for renal artery reconstruction: patch angioplasty, bypass, or replacement grafting are the options available for lesions involving the distal renal artery. The greater saphenous vein is preferred by many surgeons,[6,7] except in children where arterial autografts are now the accepted reconstructive method.[8] The hypogastric artery autograft was introduced for renal replacement at our center by Edwin J. Wylie, M.D., in 1964.[8,9] The branched internal iliac artery is uniquely suited for renal replacement. It is consistently available within the same operative field in all patients affected with distal renovascular disease. It requires no donor site replacement since its absence does not produce clinically evident pelvic or gluteal ischemia. Additionally, serial follow-up evaluation of these grafts in an enlarging patient population has documented the favorable characteristics that allow it to mimic a normal renal artery, specifically, viability (growth potential), matched compliance, and durability. For all of these reasons the hypogastric artery has been our preferred conduit for renal artery replacement for over 20 years.

There no longer appears to be any advantage to autotransplantation after complex renal artery branch repair,[9,10] although this was a popular notion and is still preferred to *in situ* aortorenal bypass by Dubernard et al.[11] Their experience is uncontrolled, sequential, and highly selective, and it does not emphasize the similar improvements in aortorenal bypass that have occurred during the two decades that encompassed their report.

The results achieved in our group of selected patients with technically challenging renovascular branch lesions support our management philosophy. Clearly, there is a range of renovascular lesions that require different interventional methods. Isolated main renal artery stenosis may be satisfactorily dilated, whereas more extensive or degenerative lesions of the main renal artery are suitable for conduit aortorenal grafting (Fig. 6). Dysplastic lesions involving the primary bifurcation are ideally suited for *in situ* replacement, preferably using the branched internal iliac artery (Fig. 4). More extensive distal lesions, reoperative lesions, and selective distal renal artery disease in solitary kidneys are ideally and safely managed by *ex vivo* renal artery reconstruction using the multibranched internal iliac artery (Figs. 5 and 6). In this cohort of patients, unique characteristics that demanded a high degree of safety included bilateral disease (25%), solitary kidneys (22%), reoperative lesions (16%), pediatric age group (9%), and significant aortic disease (7%).

These techniques will restore safely normal renal arterial anatomy with native arterial autograft material, assuring life-long normal anatomy and function for the previously threatened kidney. The strategies outlined above have reliably achieved outstanding long-term total and segmental renal salvage for patients with hypertension or aneurysmal disease. The cure/improvement response in hypertensive patients exceeds 95% and will remain so indefinitely, presumably equivalent to the patient's expected life span. *Ex vivo* reconstruction is used whenever the criteria for its use are met and *in situ* techniques are impossible. *Ex vivo* reconstruction is not a compromise to *in situ* grafting but rather a complimentary extension of this technique that is achieved with only one additional technical maneuver, the reanastomosis of the renal vein.

Acknowledgments

The authors gratefully appreciate the technical assistance of Joe Mitchell and Robert Hussing with the *ex vivo* perfusions and the assistance of Shandra Metz with the collection of patient data.

Discussion

DR. RICHARD H. DEAN (Winston-Salem, North Carolina): I rise to make three comments and ask two questions.

I congratulate Dr. Kent on an excellent presentation. The San Francisco group has one of the largest experiences in renovascular and vascular surgery in general, and we are indebted to them for presenting these data to us today.

I re-emphasize two points and stress one point not stressed in the presentation that is covered in the manuscript. The first point is the transient nature of renal dysfunction in the immediate postoperative period. We have had an experience with slightly fewer numbers. We have used *ex vivo* reconstructions in 34 patients at this point and have similarly noted a mild transient elevation in the serum creatinine levels, all of which have returned to normal by discharge. In contradistinction is the borderline patient, in whom one elects to do the *in situ* repair assuming that it can be done in an appropriate amount of time, we have noted a few patients with permanent deterioration in renal function when electing that route. I believe the point being that a more liberal use of *ex vivo* reconstructions for these patients is appropriate.

The second point is in contrast to their experience. Living in a somewhat more deprived portion of the United States than San Francisco, we have never been able to afford the Belzer pump. I would simply remind those interested members and guests that one can accomplish the same by an extremely long IV pole, a bucket of ice, and the electrolyte preservative solution hung by the same.

(Slide) I would like to stress one point that is made in their manuscript, that is, the reconstructive component of their procedure. In the initial presentations of *ex vivo* repairs, it was a technique that was married to autotransplantation. I believe the San Francisco group as well as ourselves strongly believe that this is a byproduct of the origin of these techniques from transplant surgeons. In this relatively young group in whom the replaced kidney is expected to work for five, six, or seven decades, a technique which employs a partial occlusion clamp on the vena cava, ellipse of a portion of the cava, then replacement of the kidney back in the renal fossa with reanastomosis to the tangential cavotomy, is preferable to autotransplantation to the pelvis.

I ask two questions of the authors. First, in noting that they routinely use hypogastric artery graft for all patients, I wonder if they have had any episodes of aneurysmal degeneration of their hypogastric arterial grafts. Secondly, in the patients who required bilateral procedures, I ask whether the authors would comment on whether or not they use bilateral hypogastric autografts, and if so, if they have had any late complications of this such as impotence or pelvic claudication.

DR. ROBERT C. LIM, JR. (San Francisco, California): I congratulate Dr. Stoney and his group for sharing their experience with us. I rise to emphasize that the key to his success is renal preservation.

We described a technique of *ex vivo* renal vascular surgery about 20 years ago in its selective use in trauma. Cooling the kidney with cold Ringer's heparinized saline solution was used since we do not have an elaborate perfusion pump. This remains a good technique in preserving renal function.

We, too, elect reconstruction of secondary and tertiary branches of the renal artery, then reimplanting the kidney close to its original position without disturbing the ureter.

I ask the authors one question. Do they have any thoughts or suggestions, since our technique was described 20 years ago, of improvements in preserving renal function in *ex vivo* renal surgery in a hospital where renal transplantation is not done?

DR. RONALD STONEY (Closing discussion): The comments that you just heard I believe emphasize some of the issues that we hope you would take away from this presentation, and one of them is the selective use of *ex vivo* repair in certain difficult distal lesions and *in situ* repair of more simple lesions of the primary renal bifurcation.

Dr. Dean and Dr. Lim both suggested that you might be able to achieve the same degree of renal protection using hypothermic flushing as perfusion preservation. Fred Belzer pioneered this technique in our hospital, and we, of course, have had the use of his pulsatile perfusion apparatus, which Dr. Salvatierra and I prefer, to simplify the dissection of diseased distal renal artery branches.

Hypothermic flushing will extend the ischemic tolerance of the kidney, but I believe continuous hypothermic perfusion evenly cools the entire kidney more efficiently.

The arterial autograft, in branched or straight configuration, matches the renal artery in size and branch location and thereby lends itself ideally to renal artery replacement. The ideal arterial graft requires the sacrifice of one internal iliac artery. There have been no instances of postoperative pelvic ischemia that we could detect, and we have not had occasion to remove both hypergastric arteries. If one needed a longer arterial autograft to repair renal arteries, the internal iliac and a segment of the external iliac can be harvested. The external iliac segment is thus replaced with a prosthetic graft to restore arterial continuity. It would be easier to redo a failed donor site graft repair some time later rather than redo a renal artery repair failure, which are reported following saphenous veins or prosthetic aortorenal grafts.

There have been only five males in this series of 55 patients, and impotence has not been encountered in this group, nor in other male patients 10 and nearly 20 years following hypogastric artery aortorenal grafts for main renal artery repairs that were not presented today.

The orthotopic location was emphasized by both discussants, and we agree with that method, rather than replacing the reconstructed kidney in the pelvis.

Ex vivo repair really is selective and complementary adjunct to the techniques available for main renal artery bifurcation branch repair. The method of renal preservation used depends on convenience and familiarity.

Beware of under utilizing *ex vivo* repairs for complex distal lesions as we did in a few cases. Dr. Dean correctly emphasized that slight worsening of renal function occurred only after *in situ* repairs and never after an *ex vivo* repair. We believe we can provide better renal protection particularly for kidneys that already have renal dysfunction using perfusion preservation.

The graft selected for renal artery replacement should be autogenous, and artery as well as vein are available. We believe if the goal of the reconstruction is creating a normal renal artery for the rest of the patients' life, the choice must be an arterial autograft.

3% NaCl and 7.5% NaCl/Dextran 70 in the Resuscitation of Severely Injured Patients

JAMES W. HOLCROFT, M.D.,* MARY J. VASSAR, B.S.N.,* JAMES E. TURNER, M.D.,† ROBERT W. DERLET, M.D.,† and GEORGE C. KRAMER, PH.D.‡

From the Departments of Surgery, Emergency Medicine,† and Human Physiology, ‡School of Medicine, University of California, Davis, Medical Center, Sacramento, California*

Cardiovascular resuscitation of the severely injured patient in the field remains unsatisfactory because large volumes of intravenous fluid are needed to keep up with ongoing blood losses and because only small volumes of fluid can be given. In the first study reported here, small volumes (≤ 12 mL/kg) of 3% NaCl were given to patients who were having surgery for severe injuries. The 3% NaCl restored blood pressure, pH, and urine output with approximately one half of the cumulative fluid requirement of patients who received isotonic fluids ($p < 0.05$). In a second study, 7.5% NaCl/dextran 70, 250 mL, was given in a prospective, randomized, and double-blinded trial to injured patients in the field. Blood pressure in the hypertonic/hyperoncotic group increased 49 mmHg during transport ($p < 0.005$); blood pressure in patients given lactated Ringer's solution increased 19 mmHg (NS). Survival favored the hypertonic/hyperoncotic group. The 7.5% NaCl/dextran 70 solution appears particularly promising for treatment of injured patients in the field.

CONVENTIONAL ISOTONIC FLUIDS have to be given in large volumes to resuscitate the severely injured patient. This becomes a problem in pre-hospital resuscitation because the constricted veins of the patient in hypovolemic shock make percutaneous insertion of large-bore catheters difficult. As a consequence, emergency medical personnel, using the relatively small-bore cannulae available to them, cannot infuse sufficient volumes of fluid to keep up with ongoing losses.[1,2]

A combination of hypertonic NaCl and dextran 70 could solve this problem. We have found that a combination of 7.5% NaCl and 6% dextran 70 is particularly effective in resuscitating animals from hemorrhagic shock, even when the solution is given in volumes as small as 5 mL/kg, volumes small enough to infuse in the field.[3,4] Solutions of this nature improve survival in lethal hemorrhage models[5,6] and can support circulation in an arrested hemorrhage model for at least 30 minutes[3,4]: sufficient time to keep an injured patient alive during transport to the hospital.

The two trials described in this report developed out of our laboratory work. The first trial studied the effects of infusing 3% NaCl to patients who were having surgery for acute severe injuries; the second studied infusion of 7.5% NaCl/dextran 70 to injured patients in the field.

Methods

Operating Room Study

Injured patients undergoing surgery who had had at least one episode of hypotension with a systolic blood pressure of 70 mmHg or less, or who had required resuscitative solutions in volumes exceeding 6 liters, were considered for inclusion if they: (1) were 18 years of age or older; (2) had been injured no longer than 6 hours previously; (3) had received at least 2 units of blood; (4) had received at least 15 mL/kg of crystalloid solutions during the previous hour; and (5) were likely to require at least 15 mL/kg for the next hour to maintain blood pressure and urine output.

After entry into the protocol, the patients were given, over 1 hour, either 3% NaCl (1028 mOsm/kg, 4 mL/kg) or lactated Ringer's Solution (12 mL/kg), the solution administered depending on the attending surgeon. At the end of both the first and second hour, the patient's

Submitted for publication: April 24, 1987.

fluid needs were reassessed. If at least 15 mL/kg of fluid had been required over the preceding 60 minutes to maintain blood pressure and urine output, they were given another infusion of the test solution. The test solution was withheld if the patient had required less than 15 mL/kg of fluid, or if the serum sodium concentration, as reported by the hospital laboratories, came to exceed 155 mEq/L. Thus at the end of the 3-hour study period, a patient in the 3% NaCl group could have received a total of 12 mL/kg of the hypertonic solution, although most received less. In addition to the test solution, all patients in both groups were given supplemental isotonic fluids as needed to maintain blood pressure and urine output at the best possible levels during and after the study.

The research nurse was called into the hospital for each patient, and the study was started only after she was present to make the required measurements. The predetermined hypothesis for the study was that the 3% NaCl group would achieve resuscitation with less fluid, during the infusion period, than that needed with isotonic solutions.

Field Trial

Trauma victims treated by our Life-Flight nurses, under our direction, who were transported by helicopter were considered for inclusion if they: (1) were at least 18 years old; (2) had been injured within the previous 6 hours; (3) had a sinus complex on electrocardiogram; and (4) had a systolic blood pressure of 100 mmHg or less, measured by the flight nurse at the scene or at any time during transport to the hospital. Patients were excluded if they were pregnant or if they had pre-existing hepatic, renal, cardiac, or neurological disease.

Plastic bags containing 250 mL of 7.5% NaCl/4.2% dextran 70 (2400 mOsm/kg) were prepared by the hospital pharmacist by adding 75 mL of a 23.4% NaCl solution to 175 mL of 6% dextran 70 in 0.9% NaCl. The 4.2% dextran concentration was used as we had to dilute commercially available 6% dextran to obtain the desired 7.5% NaCl concentration. These bags, and other bags with an identical appearance but containing 250 mL of lactated Ringer's solution, were then coded and placed in the hospital's Life-Flight helicopter in an order determined by a table of random numbers. Patients entered into the protocol received the solution available in the helicopter, preceded by infusion from a coded syringe of 20 mL of dextran 1[7,8] or lactated Ringer's solution, depending on the bag of resuscitative solution they were to receive. All solutions were administered *via* peripheral vein over 5 minutes or less. Supplemental isotonic fluids were administered as necessary to restore hemodynamic stability. Once the patients arrived in the emergency room, standard therapy was initiated as warranted by their clinical condition. All personnel concerned with the care of the patients were kept blinded as to the treatment solution until the code was broken on April 1, 1987. In addition to routine clinical and laboratory measurements, plasma dextran levels were determined on admission to the emergency room and at 24 hours.[9] The predetermined hypothesis for this trial was that the patient who had received 7.5% NaCl/dextran 70 would achieve higher blood pressures on arrival in the emergency room than those who received isotonic resuscitation.

All data in the text, figures, and tables are presented as means ± 1 SD. Differences over time and between groups were analyzed by a repeated measures analysis of variance on logarithmically transformed data. Differences at particular times were analyzed by a two-tailed Wilcoxon's sign test for paired data and a Mann-Whitney test for unpaired data. Survival was evaluated by a Cox proportional hazards model, and a log rank statistic test was used to test the effect of treatment over control. The analysis was made both with and without censorship of the patients with severe head injuries. Revised Trauma Scores and Injury Severity Scores were calculated using standard techniques.[10-12] Both of the studies reported here were approved by the institution's Human Subjects Review Committee.

Results

Operating Room Study

Between July 1985 and April 1986, 1156 patients were admitted to the General Surgery Trauma Service, which performed operations on 579 patients. Twenty severely injured patients were entered into the study: 10 in the 3% NaCl group and 10 in the lactated Ringer's group. The patients had similar ages, sex distributions, Glasgow Coma Scores, Revised Trauma Scores, Injury Severity Scores, mechanisms of injury, and sites of injury at time of entry (Table 1).

The only substantial difference at time of entry between the treatment groups was time from injury to time of entry, that time being longer in the lactated Ringer's group (Table 1). This time did not seem to indicate undue delay, however. The amounts of blood transfused by the time of entry to the 3% NaCl and lactated Ringer's groups were 23 ± 18 *versus* 24 ± 17 mL/kg, and the hematocrits at the time of entry were comparable (25 ± 8 *versus* 23 ± 9 vol%). Blood pressures (Fig. 1), arterial pH (Fig. 2), urine outputs (Fig. 3), fluids administered (Fig. 4), and fluid balances (Fig. 5), at time of entry, were also comparable.

By virtue of the protocol, all 10 patients in the hypertonic group received 4 mL/kg of 3% NaCl during the first hour. During the second hour, six patients received

the 3% NaCl and, during the third hour, three patients received the solution. Four patients did not receive the solution during the second hour: two had serum sodium concentrations greater than 155 mEq/L, one had required less than 15 mL/kg during the first hour for hemodynamic stability, and one had died. During the third hour, only three patients received the solution: five were hemodynamically stable and had required less than 15 mL/kg of fluid during the previous hour, and one had a serum sodium concentration greater than 155 mEq/L. All 10 patients in the lactated Ringer's group received the test solution during all time periods because all required more than 15 $mL \cdot kg^{-1} \cdot h^{-1}$ during these hours, with the exception of one patient who died in the third hour.

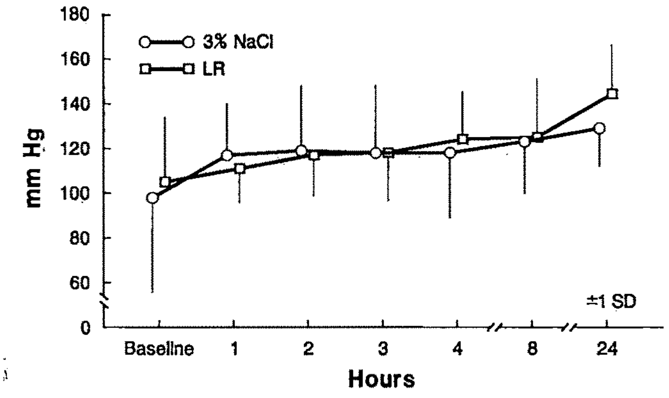

FIG. 1. Systolic blood pressure, in operating room study. Means ± 1 SD. There were no significant differences between groups.

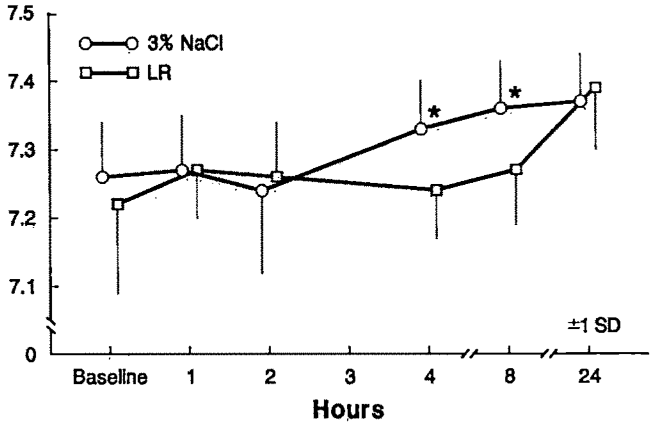

FIG. 2. Systemic arterial pH in operating room study. There were no significant differences between groups over the 24-hour period considered as a whole, by repeated measures analysis of variance, but significant differences between groups at individual time periods, by Mann-Whitney tests, as indicated by asterisks (*$p < 0.05$).

The blood pressures responded satisfactorily in both groups (Fig. 1). Arterial pH, in the face of partial pressures of CO_2 that were maintained between 38 and 42 mmHg, returned to normal sooner in the 3% NaCl group (Fig. 2). Urine outputs were greater in the hypertonic group during the time of infusion and for several hours thereafter (Fig. 3). These effects were achieved with less cumulative fluid administered in the 3% NaCl group (Fig. 4) and with smaller fluid balances (fluids infused minus urine outputs) (Fig. 5). At the end of the 24-hour resuscitation period, the 3% NaCl patients received 15 ± 12 L of crystalloid *versus* 24 ± 9 L in the lactated Ringer's group. After 24 hours, all of these differences lost their statistical significance.

Serum electrolytes, at time of entry, were comparable between the two groups and were within normal limits. Serum osmolalities, at time of entry, were slightly ele-

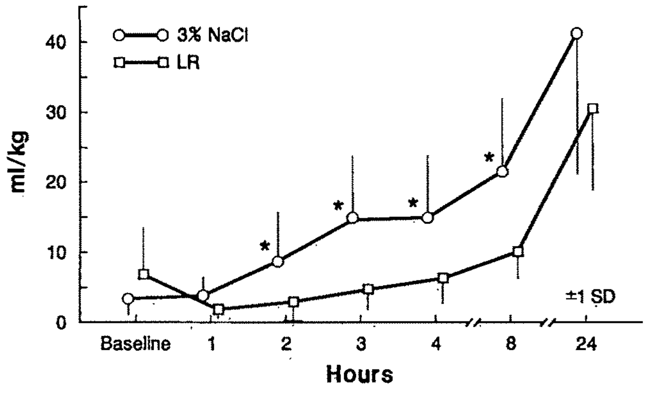

FIG. 3. Cumulative urine outputs in operating room study. There were no significant differences considering entire 24-hour period, but significant differences at individual time periods (*$p < 0.05$).

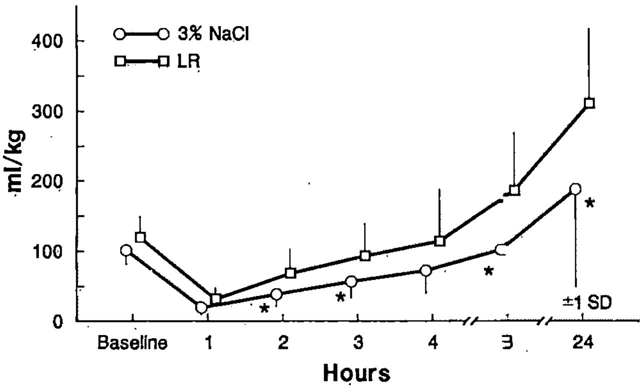

FIG. 4. Cumulative crystalloids administered in operating room study. There were no significant differences considering entire 24-hour period, but significant differences at individual time periods (*$p < 0.05$).

vated: 308 ± 20 and 303 ± 10 mOsm/kg in the 3% NaCl and lactated Ringer's groups, respectively. At 1 hour the sodium and chloride concentrations were higher in the 3% NaCl group as were the osmolalities (Table 2). These values were close to normal by 24 hours.

Modalities of treatment other than solutions administered were comparable in the two groups, including time of surgery (3.6 ± 2.1 and 5.7 ± 4.0 hours), cumulative 24-hour administered sodium (30 ± 21 and 41 ± 16 mEq/kg), and 24-hour administered blood (55 ± 91 and 60 ± 35 mL/kg). Hematocrit values at 24 hours were (28 ± 5 and 33 ± 4 vol%).

With the exception of pulmonary dysfunction, morbidity and mortality were comparable between the groups. No irritation was noted in any of the veins that were used for the 3% NaCl infusions. Seven of the patients in the 3% NaCl group and all of the patients in the lactated Ringer's group had failure of at least one organ develop after injury. Overall survival rates in the two groups were 60% in the 3% NaCl patients and 70% in the control patients.

TABLE 2. *One Hour Laboratory Data for Operating Room Study**

† $p < 0.05$.

With respect to pulmonary dysfunction, the partial pressures of oxygen in systemic arterial blood divided by the fractional concentrations of oxygen in inspired air (P_aO_2/F_iO_2 indices) were lower in the 3% NaCl group at time of entry (240 ± 131 mmHg) but held constant for the first 24 hours, when they were 256 ± 108 mmHg (Fig. 6). The P_aO_2/F_iO_2 indices were higher in the lactated Ringer's group (380 ± 135) and gradually worsened to 197 ± 94 (Fig. 6). The days of mechanical ventilation were 14 ± 20 in the 3% NaCl group *versus* 29 ± 26 in the lactated Ringer's group. Days in the intensive care unit were 18 ± 27 and 38 ± 30, respectively. Total days in the hospital were 28 ± 36 and 68 ± 56, respectively.

Field Trial

Between May 1986 and March 1987, 355 trauma patients were transported by the Life-Flight helicopter service to the University of California Davis Medical

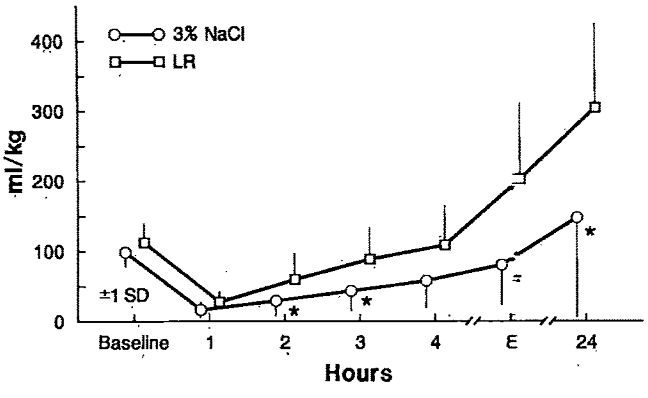

FIG. 5. Cumulative fluid balances in operating room study. There were no significant differences considering entire 24-hour period, but significant differences at individual time periods (*$p < 0.05$).

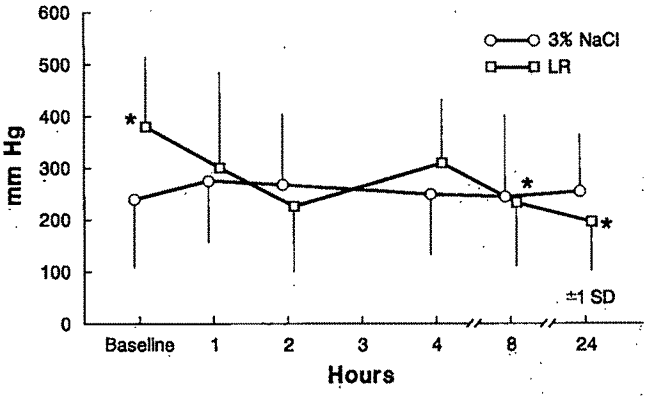

FIG. 6. P_aO_2/F_iO_2 indices in operating room study. There was a significant decrease at 8 and 24 hours in the lactated Ringer's group when compared with baseline levels (*$p < 0.05$). There was no significant decrease in indices in 3% NaCl group.

TABLE 3. *Patient Characteristics at Time of Entry into the Field Trial**

	7.5% NaCl/ Dextran 70 (N = 10)	Lactated Ringer's (N = 10)
Age (years)	25 ± 7 (19–37)	39 ± 17 (17–67)
Sex (male/female)	6/4	5/5
Time from injury (hours)	1.0 ± 0.5 (0.2–1.9)	1.3 ± 1.0 (0.3–3.3)
Systolic blood pressure (mmHg)	72 ± 29 (0–98)	69 ± 27 (0–96)
Heart rate (beats/min)	94 ± 30 (52–150)	103 ± 27 (60–150)
Ventilatory rate (breaths/min)	25 ± 6 (18–36)	27 ± 6 (24–36)
Glasgow Coma Score	10 ± 5 (3–15)	7 ± 5 (3–15)

Center. Twenty patients were entered into the study: 10 in the 7.5% NaCl/dextran 70 group and 10 in the lactated Ringer's group. Twenty-seven patients who otherwise met the criteria for entry were excluded either because of lack of venous access or other logistical problems. With the exception of incidence of severe head injuries and perhaps age, the two groups were comparable with similar sex distributions, times from injury to entry, vital signs, mechanisms of injury, and sites of injury (Table 3). With respect to neurologic status, the patients in the 7.5% NaCl/dextran 70 group had fewer serious head injuries with resulting higher Glasgow Coma Scores, higher Revised Trauma Scores, and lower Injury Severity Scores (Table 3).

The average flight times were 13 ± 8 and 18 ± 10 minutes. Nine patients in the 7.5% NaCl/dextran 70 group received the full 250 mL. One patient, with accidental disruption of his intravenous catheter, received only 125 mL. The test solution was the only fluid administered to four patients in the hypertonic group. All patients in the lactated Ringer's group received the full 250 mL of test solution. In two patients, this was the only resuscitative fluid. Figure 7 illustrates the total volumes of crystalloid administered in flight, normalizing the data for flight time. Total fluid administered during flight, without normalization for time, was 700 ± 500 mL in the 7.5% NaCl/dextran 70 group *versus* 1300 ± 900 mL in the lactated Ringer's group. The patients in the 7.5% NaCl/dextran 70 group responded with a substantial (49 mmHg) and significant ($p < 0.005$) increase in systolic blood pressure during the flight, increasing from 72 ± 29 to 121 ± 15 mmHg (Fig. 8). Blood pressures in the lactated Ringer's group increased 19 mmHg, increasing from 69 ± 27 to 88 ± 60 mmHg ($p > 0.05$, Fig. 8). Heart rates in the 7.5% NaCl/dextran 70 group increased from 94 ± 30 to 116 ± 21 ($p < 0.01$, Fig. 9); heart rates in the lactated Ringer's group remained the same (97 ± 41 and 103 ± 23). Ventilatory rates increased slightly: 24 ± 4 to 29 ± 6 ($p < 0.05$) in the 7.5% NaCl/dextran 70 group and 27 ± 6 to 30 ± 5 in the lactated Ringer's group. There was little change in the Glasgow Coma Scores: 10 ± 5 to 11 ± 5 in the 7.5% NaCl/dextran 70 group and 7 ± 5 to 7 ± 5 in the lactated Ringer's group. None of the patients in either group died during transport.

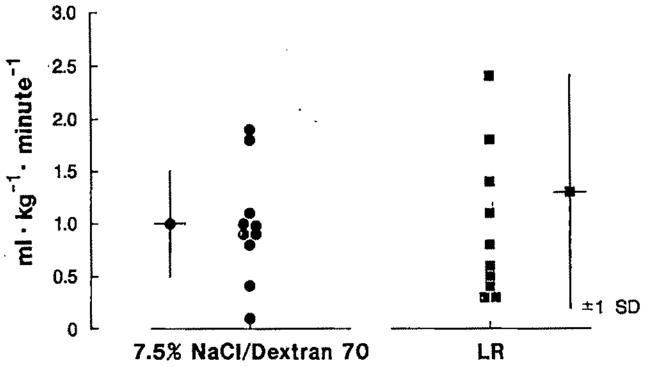

FIG. 7. Fluid administered during helicopter flight in field trial, as $mL \cdot kg^{-1} \cdot min^{-1}$ to compensate for flight time. Individual patients with means ± 1 SD.

The serum sodium concentrations, chloride concentrations, and osmolalities were significantly elevated by time of admission to the emergency room in the 7.5%

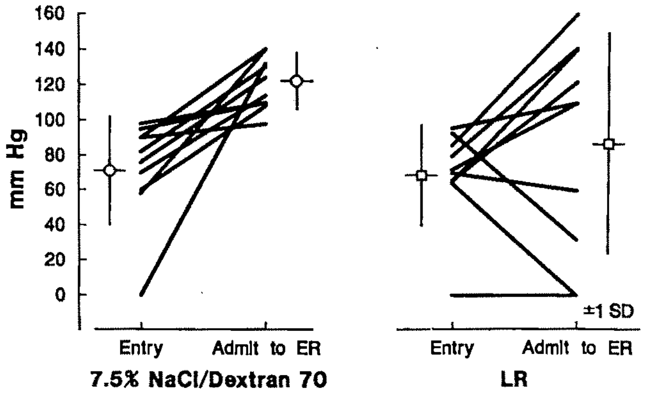

FIG. 8. Systolic blood pressures in field trial. There was a significant increase ($p < 0.005$) in patients given 7.5% NaCl/dextran 70.

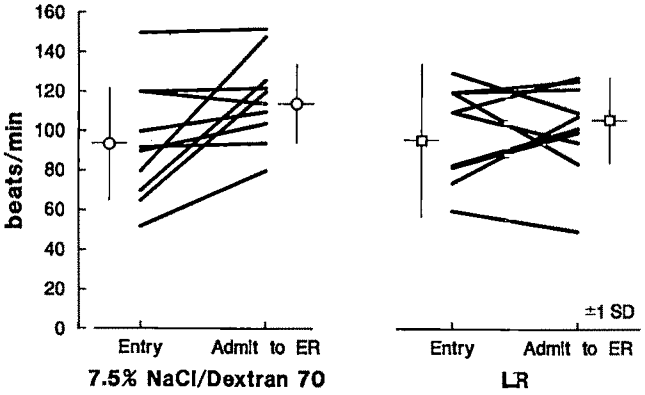

FIG. 9. Pulse rates in field trial. There was a significant increase ($p < 0.01$) in patients given 7.5% NaCl/dextran 70.

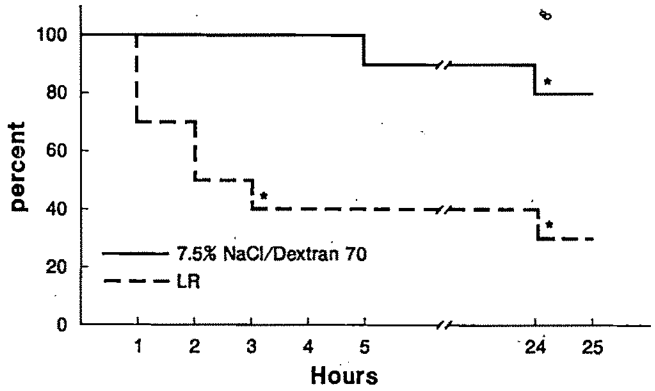

FIG. 10. Survival in field trial. Asterisks represent patients with severe head injuries who were allowed to die at the times indicated. All patients who survived the first 24 hours are still alive.

NaCl/dextran 70 patients (Table 4). These abnormalities were well resolved within several hours. The serum potassium levels were less than 3.5 mEq/L in three patients in the 7.5% NaCl/dextran 70 group, the lowest being 2.9 mEq/L. No ventricular dysrhythmias developed with the hypokalemia. Plasma dextran levels in the 7.5% NaCl/dextran 70 group, on admission to the emergency room, were 3.0 ± 0.7 mg/mL (N = 10); by 24 hours they had fallen to 0.9 ± 0.4 (N = 8). No preinfusion laboratory values are available.

Two alert patients in the 7.5% NaCl/dextran 70 group remarked on a sensation of warmth in their extremities during the infusion, and the nurses reported marked flushing in four patients who received the hypertonic solution. These symptoms were transient. No phlebitis developed in any veins used for the infusions. There were no type or cross-matching problems.

Survival of the patients in the two groups is shown in Figure 10. One patient in the 7.5% NaCl/dextran 70 group died at 5 hours with disseminated intravascular coagulation; the second patient was allowed to die at 24 hours with a severe head injury. One patient in the lactated Ringer's group, with no blood pressure in the field and none in the emergency room, died in the operating room at 1 hour with a shotgun wound to the abdominal aorta and inferior vena cava. One patient died at 1 hour in the operating room with a ruptured left ventricle; and one patient died at 1 hour from a severe head injury. One patient in the lactated Ringer's group died at 2 hours with a severe head injury; a second patient died at 2 hours with disseminated intravascular coagulation. The remaining two deaths in the lactated Ringer's groups, at 3 and 24 hours, were in patients who were allowed to die with severe head injuries. Overall survival was better ($p < 0.05$) in the 7.5% NaCl/dextran 70 group, even when censoring the patients with severe head injuries.

TABLE 4. *Laboratory Data for Patients in Field Trial at Time of Arrival in the Emergency Room**

	7.5% NaCl/Dextran 70	Lactated Ringer's
Serum sodium (mEq/L)	153 ± 4 (144–159)†	142 ± 5 (32–150)
Serum potassium (mEq/L)	3.6 ± 4 (2.9–4.4)	3.9 ± 0.3 (3.5–4.3)
Serum chloride (mEq/L)	119 ± 5 (106–127)	109 ± 6 (98–117)
Osmolaltiy (mOsm/kg)	337 ± 23 (313–358)	315 ± 28 (279–345)
pH	7.27 ± 0.09 (7.10–7.40)	7.34 ± 0.30 (7.06–8.04)
Hematocrit (vol%)	28 ± 7 (16–38)	31 ± 8 (20–41)

Discussion

This is not the first report of using hypertonic sodium chloride solutions in humans. In the 1920s, Silbert,[13] working at Mt. Sinai Hospital in New York City, used peripheral intravenous infusions of 5% NaCl to treat patients with Buerger's disease. Injections in volumes as large as 300 mL, given over periods as short as 10 minutes, produced flushing and warmth in both ischemic and nonischemic parts of the body but produced no instances of phlebitis and no neurologic abnormalities. Later on, hypertonic sodium-containing solutions were used for correction of electrolyte abnormalities and, by the 1970s, moderately hypertonic solutions were being used to resuscitate patients with severe burns.[14] In 1980, deFelippe et al. reported that a 7.5% NaCl solution, in a volume of 4 mL/kg, was effective in resuscitating patients in hypovolemic shock.[15] In 1983, Shackford et al., in a well-controlled study, reported on the use of a 1.5% sodium-containing solution to maintain cardiovascular stability in patients who had elective vascular surgery.[16]

We used a 7.5% NaCl/dextran 70 solution in the helicopter study because combinations of hypertonic sodium salts with dextran 70 are the most effective fluids that we have found for resuscitation of animals from shock. Such a solution, when given to animals in shock, dramatically restores blood pressure and cardiac output within 2 minutes of infusion.[3,4] It also restores acid-base balance, urine output, and oxygen consumption.[4] A 7.5% NaCl/6% dextran 70 solution has a calculated osmolality of 2400 mOsm/kg, the dextran adding only 1 mOsm/kg to the tonicity.[17] Its oncotic pressure, generated solely by the dextran, is about 75 mmHg, a high value created by the properties of the long chain polysaccharides moieties and a value substantially greater than that expected based on their concentrations and molecular weights.[17] The immediate beneficial effects of these hypertonic/hyperoncotic solutions arise from the hyperosmolality *per se* and are generated by plasma volume expansion,[3,4,18-20] enhancement of myocardial contractility,[21-25] and augmentation of organ blood flow mediated by dilation of precapillary resistance vessels.[21,26-30] These hyperosmolar-induced benefits dissipate within 15 minutes, however, as plasma volume reverts to shock levels.[3] The addition of dextran 70 to the 7.5% NaCl prevents this deterioration,[3] and the beneficial effects of the hypertonic/hyperoncotic combination can easily last for 30 minutes,[4] at least in arrested hemorrhage models. This would be enough time to transport most patients to the hospital.

The results of the operating room and helicopter trial are consistent with and support the conclusions reached in the animal work and suggest that a hypertonic NaCl/hyperoncotic dextran combination may be beneficial in the field treatment of severely injured patients. The 3% NaCl solution produced excellent resuscitation of severely injured patients with good restoration of blood pressure, acid-base balance, and urine output, and achieved these beneficial effects with less fluid during the resuscitative phase than that required with conventional isotonic fluids. The 7.5% NaCl/dextran solution was safe in the prehospital setting and produced substantially higher blood pressures than those produced by conventional treatment despite the control patients being given substantial amounts of isotonic fluid. The 7.5% NaCl/dextran 70 solutions also appeared promising with regard to improving survival (Fig. 10).

Administration of a solution of this sort to patients does pose certain theoretical risks, however. The dextran could cause bleeding abnormalities and could interfere with cross-matching of blood. The hypertonicity of the solutions could cause phlebitis. Rapid increases in osmolalities and in serum sodium and chloride concentrations could induce neurologic abnormalities,[31-33] and rapid expansion of the extracellular space could produce hypokalemia[4,34] and arrhythmias. Lastly, rapid restoration of blood pressure and perfusion could lead to resumption of bleeding from severed vessels that had gone into spasm or that had clotted with the initial shock insult.

None of these theoretical risks[35-38] was realized in any of the patients, as best we could determine. The amount of dextran administered was small and resulted in low plasma dextran concentrations. No unexplained clotting abnormalities developed in any of the patients,[35,38] and the blood bank had no difficulty in cross-matching blood.[36,37] Hypertonicity by itself does not necessarily induce phlebitis if infusion times are limited. Radiographic contrast media have osmolalities approaching that of the 7.5% NaCl/dextran 70 solution, as does the sodium bicarbonate (1800 mOsm/kg) that is used in resuscitation of patients from cardiac arrests. The 7.5% NaCl/dextran solution does not cause phlebitis in animals,[39] and we found none in our patients. It would seem important, however, to avoid extravasation.

Osmolalities and serum sodium and chloride concentrations increase rapidly with infusion of these solutions, but this should not necessarily be a problem. Rapid increases in osmolality can damage the central nervous system, but, to our knowledge, this has only occurred in patients who have had very low serum sodium concentrations (less than 115 mEq/L) before the onset of hyperosmolality or in patients with established liver disease.[33] None of our patients had chronic hepatic or cardiac disease (and it would seem wise not to use these hypertonic solutions in patients with obvious signs of cirrhosis or congestive heart failure). We noted no central nervous system abnormalities that could have been attributed to the infusions. The Glasgow Coma Score even improved slightly, but insignificantly, in the patients given the hypertonic solutions, consistent with the finding that hypertonic sodium-containing solutions reduce intracranial pressures in animals resuscitated from shock.[40-42]

Some of our patients became modestly hypokalemic with the infusions, probably because the resuscitative fluid is potassium free and because it rapidly expands the extracellular space.[4,34] The solution did not cause any arrhythmias, and rapid expansion of plasma volume is probably worth the risk of hypokalemia in patients with major hemorrhage. Nonetheless, it currently would seem best to use these solutions with care in patients who might be taking digitalis compounds. The risk of rebleeding with re-establishment of blood pressure did not seem to be a problem in these studies.

In summary, small volumes (≤ 12 mL/kg) of 3% NaCl, when given to patients who have surgery for severe injuries, restored blood pressure, pH, and urine output with approximately one half of the cumulative fluid requirement of patients who received isotonic fluids. In a field trial, administration of 7.5% NaCl/4.2% dextran 70, in even smaller volumes (250 mL), resulted in augmented blood pressures during helicopter transport and tended to improve survival when compared with the lactated Ringer's group. This solution appears promising for the field resuscitation of injured patients.

Acknowledgments

We thank the Life-Flight nurses, Colleen Perry, B.A., and Dr. Wayne Gannaway of Pharmacy Services at the University of California, Davis, Medical Center, Sacramento.

Discussion

DR. GEORGE F. SHELDON (Chapel Hill, North Carolina): This is a useful study as it addresses both the conceptual and logistic problems of prehospitalization resuscitation. Most studies of prehospital resuscitation show that in severely injured patients it takes about 10 minutes to initiate intravenous therapy. Initiation of intravenous therapy before arrival at the hospital results in less than 1 liter of fluid actually being administered.

It is of interest that in this study 1300 mL of the Ringer's lactate control were administered, which puts it well outside of the usual amount that most patients receive during pre-hospital resuscitation. A solution that will maintain hemodynamic integrity with low volume is of potential use. The authors are to be congratulated for a well-designed, difficult study.

I have several questions. Dr. Holcroft alluded to the fact that there appeared to be some direct effect on the myocardium from the solution. Some years ago, Dr. Samuel Powers, just before his death, was using dextran and observing effects in shock resuscitation of dextran directly on the myocardium. I believe most of that work was not completed. I wonder if Dr. Holcroft could speculate on the mechanism of dextran effect on the heart?

I am surprised the earlier studies showed membrane potential returning to normal with hypertonic resuscitation fluid because one would postulate that fluid would be drawn from the cell. Perhaps Dr. Holcroft could give us an explanation.

Finally, what is the limit of the amount of fluid that can be safely administered? As Dr. Clowes suggested, when a new fluid resuscitation routine comes along, great potential for misuse exists. I hope that the usefulness demonstrated in this study is not subverted into inappropriate use; perhaps the most obvious inappropriate use that might occur would be giving volumes that were excessively hyperosmolar in inappropriate amounts.

I believe this is an important study that addresses a significant problem.

DR. DONALD TRUNKEY (Portland, Oregon): I was intrigued by this study and had the opportunity to review the manuscript. Dr. Holcroft has shown that hypertonic saline and dextran combination has a major advantage in the prehospital setting and more probably in the combat situation, where small volumes could do what larger volumes in the past have been required to do.

The thing that is unique about this study is that he has shown that this combination of drugs or resuscitation fluids has a very positive contribution to increased flow. Specifically, he showed in his animal study and then in his flight study that there is a decrease in systemic vascular resistance that is probably due to the hypertonic saline. He showed a tendency toward an increase in heart rate, and both of these mechanisms could clearly increase flow.

He has not addressed in his paper stroke volume, although one would presume that would be increased with the increase in volume or plasma refill, but it was not specifically measured.

The questions that come out of this study are multiple but I would like to confine my questions to three or four.

In his manuscript Dr. Holcroft shows the PO_2/FIO_2 ratio was higher in the Ringer's lactate group, but then it dropped.

The question is: was central venous pressure kept within normal ranges? I cannot explain why the P_aO_2/FiO_2 ratio was initially better in the Ringer's lactate group than the hypertonic saline group and then fell significantly lower.

What happened to pulmonary vascular resistance? Did it fall as did systemic vascular resistance? Was there an effect on the microemboli insult to the lungs? If you did measure pulmonary vascular resistance then what role does dextran have? Is it acting as a rheologic agent in the pulmonary vasculature? Is it acting as a free radical scavenger?

Finally, did you measure extravascular lung water in these patients once they were resuscitated?

My only concern is that you did show a statistical significance in regards to the survivability in the hypertonic saline group. Do you have a type 2 error because of the small numbers?

DR. JAMES D. HARDY (Jackson, Mississippi): (Slide) I rise to offer additional support to the results and conclusions presented in this excellent report.

Some years ago, we infused in 17 patients 1 L of 3% sodium chloride over 1 hour (Surg Forum 1955; 5:465). Total body water was measured with heavy water, extracellular fluid was measured with sodium thiocyanate, and plasma volume was measured with Evans blue dye.

It may be seen that the 3% sodium chloride reduced intracellular fluid from the average of 21 L to 16 L. Of course, this reduction is based on the thiocyanate space measurement. Extracellular fluid increased from 15 L to 20 L, and plasma volume increased from 3 L to 4 L.

To be certain, this methodology has been improved over the past 30 years, but the sizes of these changes indicate that 3% sodium chloride does, in fact, change these spaces.

DR. PAUL R. SCHLOERB (Rochester, New York): Dr. Holcroft has provided convincing evidence of the superiority of hypertonic saline over isotonic lactated Ringer's. My question is: why didn't you use hypertonic lactated Ringer's solution?

DR. FRANCIS D. MOORE (Boston, Massachusetts): I thank Dr. Blaisdell and Dr. Holcroft for this paper and for allowing me to look over the manuscript.

During World War II, Taber and Rosenthal, working for the Office of Scientific Research and Development (which later became the NIH extramural grants program), did a study in burned rats and mice showing that hypertonic saline would produce rapid resuscitation.

This was not taken up clinically and was not used often. Periodically since then about once every 10 years, there has been a flurry of interest in this topic and the rediscovery of the hypertensive effects of hypertonicity.

I congratulate Dr. Holcroft and Dr. Blaisdell for their work. I also congratulate and in a sense commiserate with the physiologic mechanisms of the human body that has learned to tolerate an injection intravenously of sea water, which has been known for thousands of years to be lethal if taken internally.

Sea water is about 3% sodium chloride, a sodium concentration of about 600 mEq/L, about four times that of isotonic solution. Here, our surgical colleagues were up to higher than that in their prescription for intravenous salt.

The body can only do two things when faced with such a potentially lethal hypertonic load: excrete and dilute. Do not forget that progressive hypertonicity is always fatal when the sodium goes over about 175–180 mEq/L. This has been a mechanism of death in everything from newborn nurseries to castaways in the ocean or in the desert.

The water for this dilution comes in part from cell water as they believed, and as Dr. Hardy's study nicely demonstrates, but not entirely. This new water also arises by sucking water out of transcellular spaces in other parts of the body (joints, gut, brain) into the PV and ECF. However, there is a limit and you cannot go on doing that forever. Therefore, you must provide new water in moderation to float out the salt without overhydrating the patient.

As to excretion, their manuscript shows that their patients' kidneys were working overtime to keep up with this tremendous load of salt by excreting urine (probably hypertonic) in large quantities. I would be interested to know what the composition of that urine is.

So the body can "take it." If the load is not too serious, it will live through it! And, the body gets a blood pressure boost. I agree that hypertonic sodium salts have a pharmacologic effect. Do not ever underestimate the pressor effect of the sodium ion.

My main concern about this paper is the concept that this sort of treatment should be used "in the field." In what field? In a battlefield, the wounded (lying often in the jungle or the desert) are terribly thirsty. They are always missing water. They crave water, spring water, clear water, sodium-free water. If this highly concentrated salt solution is given to larger numbers of military casualties who cannot get to water they are going to get severely hypertonic and die in hallucinations with high fever and plasma sodium concentration over 175 mEq/L. They can be restored to normal by giving some free water or some water with a low amount of sodium.

This method is interesting. It has been tried before. It is a pressure boost. These workers have done a good job of showing us what a boost it gives. However, to give this dangerous challenge to large numbers of wounded people who do not have any access to the water that will let their bodies handle this intravenous load of sea water could be potentially lethal. We should be very cautious about recommending it too widely.

DR. WILLIAM STAHL (Bronx, New York): I congratulate Dr. Holcroft. We did the same study in dogs using a more severe model. We have mostly penetrating injury in our trauma center. Humans bottom out in 10 minutes; therefore, we bottomed the dogs out in 15 minutes and randomly assigned them to Ringer's solution, hydroxyethyl starch, or a mixture of hydroxyethl starch and 3% salt.

These animals were kept bleeding 15 minutes "on the street," 15 minutes "in the bus," 15 minutes "in the emergency department," before we stopped the bleeding. There is no question that the mixture of colloid and hypertonic salt restores cardiac index as well as blood pressure and produces better perfusion. I believe that with a little safer concentration of salt, 3% *versus* 7.5%, and the addition of some colloid, you can optimize the method for expanding volume.

In these animals we gave the amount equivalent to what you would give during ambulance transportation. That is 1 L to 1200 mL for an average adult, with no untoward effect. I agree that too much hypertonic salt might be a problem. We discontinued the hypertonic solution as soon as the animals theoretically reached the emergency department. However, I believe for the short term, limited volume, resuscitation, the combination of 3% salt, and colloid is a better solution.

DR. G. TOM SHIRES (New York, New York): May I just say Dr. Moore and I have not always agreed initially, but we have usually agreed ultimately. This time, without any data, I agree with him initially and totally. Like Dr. Moore, we have seen a lot of things, hypertonic and extraneous, come and go: everything from oxypoly gelatin to polyvinylpyrrolidone to hypertonic solutions, and as Dr. Moore said, they seem to cycle about once a decade and then they fade into oblivion. Maybe this one will be different. I do not have any data, and I do not believe Dr. Moore was quoting any, other than what we know from evolution, and I happen to agree with him wholeheartedly.

DR. GEORGE H. A. CLOWES, JR. (Boston, Massachusetts): Dr. Holcroft, I ask you briefly whether you have any evidence as to whether the beta-adrenergic activity is actually increased under these circumstances to account for the tachycardia?

DR. JAMES W. HOLCROFT (Closing discussion): Dr. Sheldon and Dr. Clowes, we do not know what the effects are on the heart yet. We believe they are mediated by beta-adrenergic receptors, but other than that, we cannot say. If the solution is given to rats that have been subjected to severe hemorrhagic shock, the solution completely restores deteriorated membrane potentials. Furthermore, it mobilizes shock-sequestered intracellular sodium and chloride. That is, animals given this hypertonic solution actually end up with less sodium and chloride inside their cells than animals given equivalent amounts of salt in an isotonic solution. How often can the fluid be given? In sheep we have given it on multiple occasions. The best response is with the first administration. After that, the solution does not work as well.

Dr. Trunkey, we do not have measurements of cardiac indices, extravascular lung waters, pulmonary vascular resistances, or any of the other hemodynamic measurements that we would like to have in these patients. The patients in both studies could not be monitored thoroughly. The role of dextran in the animals is very convincing. If you give pure 7.5% sodium chloride to sheep, you will get an excellent transient response, but that response dissipates within 15 minutes. Adding dextran allows those beneficial effects to last for at least 30 minutes.

Dr. Hardy, thank you. There is nothing new under the sun. In fact, Dr. Silbert, working in Dr. Berger's hospital in New York City in 1926, published his experience with infusion of 5% sodium chloride, using much the same total sodium dose that we currently are proposing to use in the field management of severely injured patients.

Dr. Schloerb, we have tried hypertonic acetate in combination with hypertonic sodium chloride in the sheep. The results favor the hypertonic sodium chloride slightly. Because of those early sheep experiments, we have continued to work with the sodium chloride rather than adding lactate or acetate.

Dr. Moore, we believe that the solution works, in part, by drawing water out of the lumen of the gastrointestinal tract. Many of these patients had been drinking before their accident. We believe that this is one reason why the solution worked so well. We agree that the solution should not be used in dehydrated individuals.

Dr. Stahl, I appreciate your comments. These patients not only are in shock when you pick them up, but they continue to bleed. The patients that are most likely to benefit from the solution are those who are the worst off to begin with.

Recognition and Treatment of Patients with Hereditary Nonpolyposis Colon Cancer (Lynch Syndromes I and II)

ROBERT J. FITZGIBBONS, JR., M.D., F.A.C.S., HENRY T. LYNCH, M.D., GREGORY V. STANISLAV, M.D.,
PATRICE A. WATSON, PH.D., STEPHEN J. LANSPA, M.D., JOSEPH N. MARCUS, M.D., THOMAS SMYRK, M.D.,
MARY D. KRIEGLER, B.S., R.N., and JANE F. LYNCH, B.S., R.N.

Primary genetic factors are etiologic in at least 5–10% of patients with colon cancer. The polyposis syndromes (FPC) are easily identified examples because of the spectacular number of polyps. The hereditary nonpolyposis syndromes (HNPCC), although five times more common than FPC, are usually not recognized because they do not have such a distinctive clinical, premonitory genetic marker. Colorectal cancer expression was surveyed in 10 extended, thoroughly documented HNPCC kindreds. One hundred sixteen patients were found to have 183 colorectal cancers. Despite the striking family history, less than 5% were correctly treated by subtotal colectomy. This provided a unique opportunity to study the natural history. Five findings differed significantly ($p < 0.05$) from patients with sporadic colon cancer: (1) mean age of initial colon cancer diagnosed was 45.6 years; (2) 69.1% of first colon cancers were located proximal to the splenic flexure of the colon; (3) 18.1% had synchronous colon cancer; (4) 24.2% had metachronous colon cancer develop with life table analysis showing the risk for a metachronous lesion at 10 years to be 40%; and (5) only 23.3% of cancers were located in the sigmoid colon or rectum. Based on this data, it is recommended that the family history of all patients with a newly diagnosed colon cancer be evaluated for evidence of this syndrome. If an autosomal dominant inheritance pattern emerges, an in-depth genetic investigation is indicated. When HNPCC is confirmed, the following recommendations apply: a subtotal abdominal colectomy is indicated at the time of the initial colon cancer because of the risk of synchronous and metachronous lesions. The rectum should be spared in favor of careful lifetime surveillance because of the proclivity for proximal colon cancer involvement. As yet unaffected members of a newly diagnosed HNPCC kindred who are in the "direct genetic line" should be cautioned that they are at 50% risk and must begin an intensive surveillance program beginning in the third decade with careful attention to the right colon. Patients from newly diagnosed HNPCC families who have had a previous conventional colectomy for colon cancer should, at the very least, enter an intensive surveillance program; a prophylactic completion subtotal colectomy should be considered for patients who are less than totally compliant.

From the Departments of Surgery, Medicine, Pathology, and the Hereditary Cancer Consultation Center, Creighton University School of Medicine, Omaha, Nebraska

IT IS ESTIMATED that colorectal cancer will develop in 145,000 patients in the United States in 1987. Sixty thousand individuals will die of the disease.[1] Five to ten per cent of these malignancies are now recognized as being hereditary.[2] A fraction of these patients from this hereditary subset are members of families with familial polyposis coli (FPC) or a related syndrome and are thereby easily recognized because of the distinctive clinical marker of multiple adenomatous polyps. Unfortunately, hereditary *nonpolyposis* colon cancer (HNPCC), which is more than five times as common as FPC, does not have such a distinctive clinical marker.[3] Thus, a patient with a newly diagnosed colon cancer who is a member of an HNPCC kindred may not be recognized as such and is inappropriately treated with a conventional colectomy as one would recommend for sporadic colon cancer.

The purpose of this paper is to make recommendations concerning first, the recognition of patients with HNPCC by simple analysis of the family history and second, management strategy that is distinctly different from FPC or sporadic colon cancer. These recommendations are based on an in-depth analysis of 10 HNPCC kindreds to determine the natural history of the condition.

Methods and Materials

The study population consists of 10 kindreds followed at the Creighton University Hereditary Cancer Institute. The index patient was referred by either a physician or a

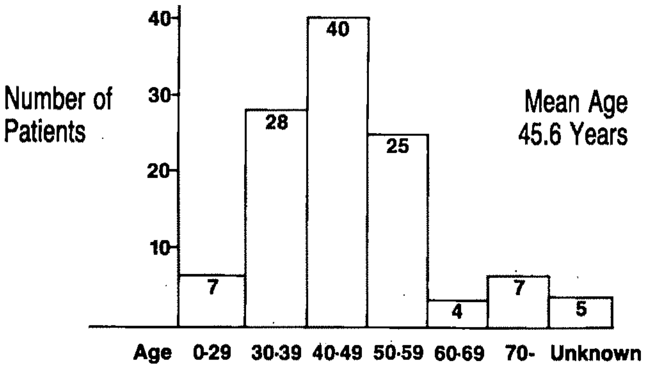

FIG. 1. Age distribution at the time of initial colon cancer diagnosis.

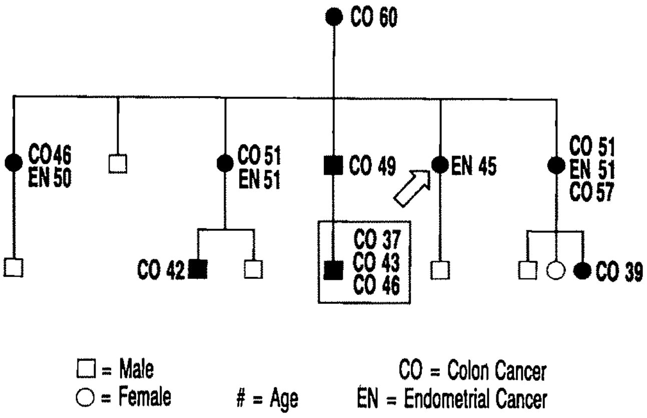

FIG. 3. A partial family pedigree of one of the HNPCC kindreds in this study. The patients highlighted by the box and the arrow are discussed in the text.

member of the family because of a perception of an inordinately high incidence of cancer. The patients with colon cancer in these families were uniquely suited for study of the natural history of HNPCC because less than 5% were treated appropriately by subtotal colectomy at the time of initial diagnosis. Extensive pedigree analysis through multiple generations disclosed that these 10 families fulfilled previously defined criteria of HNPCC.[4] Verification of family reports of cancer was accomplished whenever possible by primary medical document review including medical records, operative notes, pathological reports, and autopsy and death records.

Statistical Methods

Descriptive statistical methods were used in the analysis of these data. Categorical variables were described with frequency distributions and proportions; continuous variables (*i.e.*, age) were described additionally in terms of means and standard deviations. Inferences about differences from the unselected population of colon cancer cases were made by establishing 95% confidence intervals and comparing these with the closest comparable values found in the general population literature.[1,5-7] The incidence of metachronous colorectal cancer was also described using life table analysis, taking the initial colorectal diagnosis as the start of observation and calculating risk over a specified interval as cumulative proportion surviving through that interval subtracted from one.

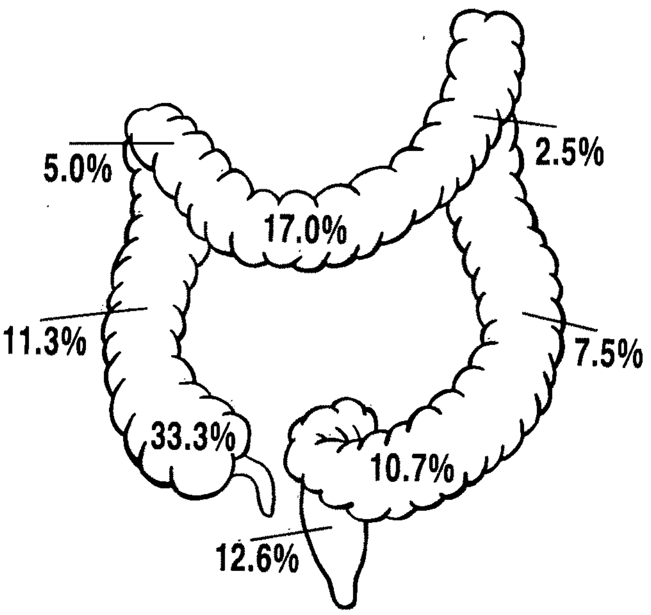

FIG. 2. Location of the first colon cancer in 113 patients. Three patients are not included because the site could not be unequivocally documented.

Results

One hundred sixteen individuals were identified with 183 histologically confirmed colorectal cancers. There were 52 females and 64 males. Mean age of colon cancer onset was 45.6 years. The age distribution is depicted in Figure 1. The location of the first colon cancer was unequivocally documented in 113 of the 116 patients. The distribution is shown in Figure 2; 69.1% were located proximal to the splenic flexure and only 23.3% involved the sigmoid colon or rectum. Synchronous colon cancer was defined as any additional colon cancer occurring within 1 year of another. Thirty-three colon cancers in 21 patients fit this description for a synchronous colon cancer rate of 18.1%. If a colon cancer was diagnosed more than 1 year after a preceding colon malignancy, it was considered metachronous. This was found in 34 colon cancers in 28 patients for a metachronous colon cancer rate of 24.2%. Life table analysis disclosed the cumulative incidence of metachronous colon cancer to be 40% by 10 years. Colon cancer incidence was consistent with an autosomal dominant inheritance pattern in all 10 families, and representative pedigrees are depicted in Figures 3 and 4. Extracolonic cancers were found in

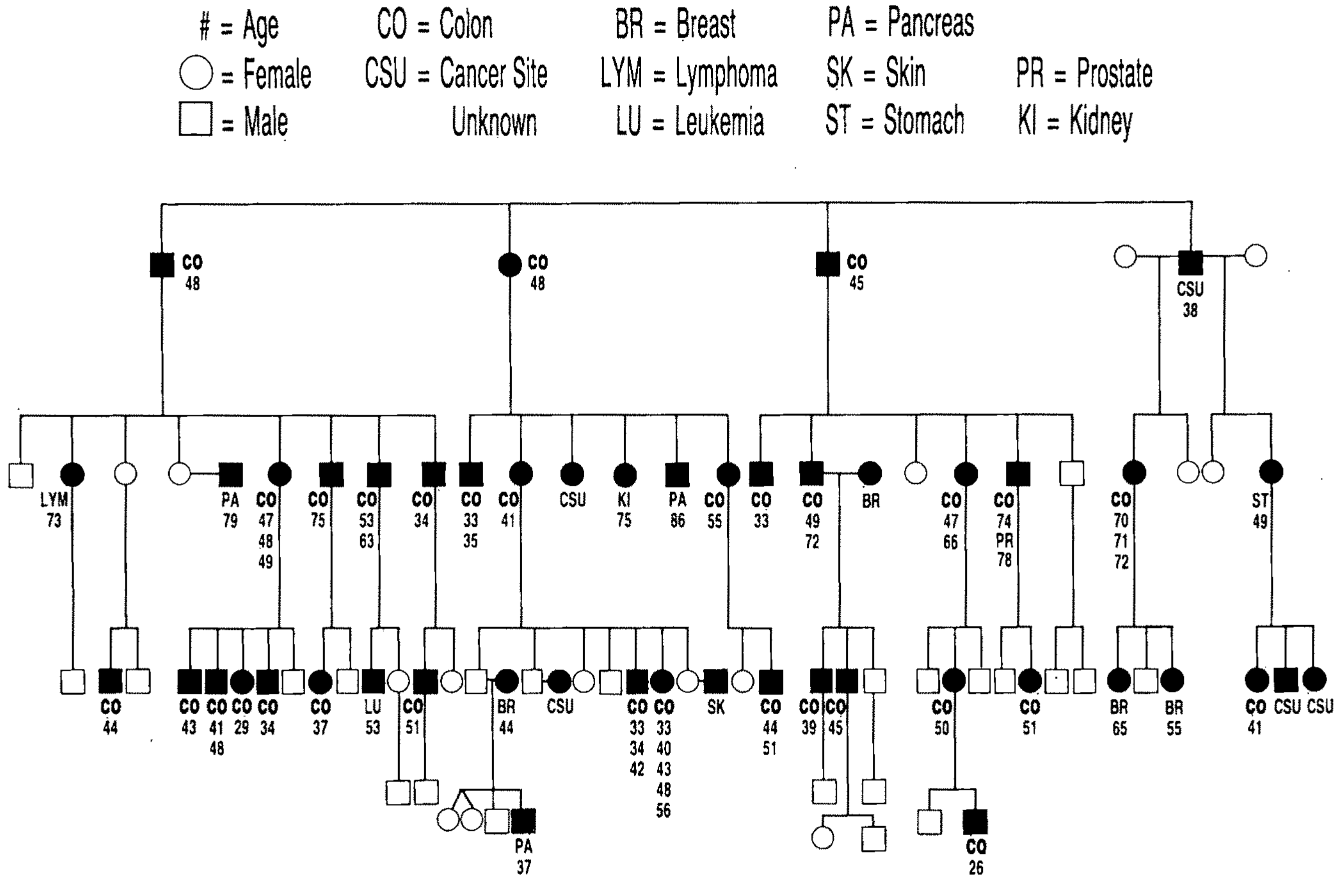

FIG. 4. A partial family pedigree of another family in this study. The multiple operative procedures necessitated by the synchronous and metachronous colon cancers could have been avoided if the presence of the syndrome was appreciated at the initial diagnosis.

151 members of the 10 families with an unusually high incidence of female genital tract lesions, *e.g.*, 32 endometrial cancers. Table 1 reflects the distribution of all cancers. The findings of early age of onset, proximal colon involvement, relative sparing of the sigmoid colon and rectum, and the high incidence of synchronous and metachronous colon lesions differed significantly at the $p < 0.05$ level when compared with representative published reports dealing with sporadic colon cancer[5–7] (see Table 2).

TABLE 1. *Comparison of Distribution of Cancers with the General Population*

Site (No.)	HNPCC Patients (%)	1987 Estimate for General Population[1] (%)
Colon and rectum (183)	55	15
Female genital tract (45)	14	7
Skin (19)	6	3
Lymphoma, leukemia (9)	3	5
Breast (17)	5	14
Stomach (13)	4	2
Urinary tract (17)	5	18
Pancreas (4)	1	3
Lung (1)*		15
Miscellaneous (11)	3	18
Cancer site unknown (15)	4	
Total (334)	100	100

* The curiously low incidence is currently under investigation.

Discussion

HNPCC is a syndrome that affects a significant percentage of the total colon cancer population but is not

TABLE 2. *Significantly Different Findings ($p < 0.05$) Between the Patients in this Study and Sporadic Colon Cancer Patients*

Finding	HNPCC Patients	Sporadic Colon Cancer Patients*
Age of first colon cancer diagnosis	45.6	63.0
Location proximal to the splenic flexure of the colon	69.1%	28.6%
Location in the rectum or sigmoid colon	23.3%	66.3%
Synchronous colon cancer	18.1%	4.8%
Metachronous colon cancer	24.2%	7.7%

* From representative published reports dealing with sporadic colon cancer.[5–7]

easily recognized because it lacks a distinctive clinical marker such as multiple polyps. It is important that physicians caring for patients with colon cancer appreciate its subtle presentation because the treatment for affected individuals is different than sporadic colon cancer and its autosomal dominant inheritance pattern allows the use of Mendelian genetics to make accurate predictions concerning risk for other members of the family. The incidence can be appreciated best if one divides the total colon cancer burden into four types: (1) sporadic, 70–80%; (2) familial, which represents those patients who have at least two first-degree relatives with a history of colon cancer without a clearly definable genetic inheritance pattern, 10–20% (3) hereditary colon cancer of the polyposis variety (FPC), slightly less than 1%; and (4) HNPCC, 5–6%.[4]

The natural history of HNPCC delineated by the data in this study suggests several cardinal features: (1) proximal colonic cancer involvement, (2) increased incidence of synchronous and metachronous colon lesions, (3) early age of onset, and (4) autosomal dominant genetic transmission. Extracolonic adenocarcinomas are associated in some of the families. The relationship is best understood if HNPCC kindreds are divided into two syndromes: (1) Lynch Syndrome I (Hereditary Site Specific Colon Cancer), which is characterized by an increased incidence of colon cancer, only, and (2) Lynch Syndrome II (the Cancer Family Syndrome), which is the same as Lynch Syndrome I with respect to colon cancer but is also associated with an increased risk for selected extracolonic adenocarcinomas that develop at a relatively early age and are inherited integrally (*i.e.*, on the same gene) with the colon cancer. The endometrial cancer in the family depicted in Figure 3 serves as an example. In this study, only female genital cancers were inherited in this fashion. However, breast, pancreas, and other cancers have been reported to act the same way in other families.[4] Once the cardinal features of HNPCC, as well as the relationship to extracolonic carcinomas, are appreciated, it is possible to recognize patients who are members of an affected family and then make appropriate treatment recommendations which, for the colon, are different than one would make for the same patient with a sporadic or familial colon cancer or hereditary colon cancer of the polyposis variety.

Recognition of Patients with Hereditary Nonpolyposis Colon Cancer

A surgeon faced with a patient who is a member of an HNPCC kindred with a newly diagnosed colon cancer will not make a correct management decision regarding the appropriate operative procedure unless the presence of the syndrome is appreciated. Unfortunately, no specific biomarkers are available for screening. Thus, the physician must depend entirely on the patient's family history. A relatively young patient with a proximal colon lesion is the first clue that should arouse suspicion. The next step is to inquire about the family history with specific attention to the presence of an autosomal dominant inheritance pattern and the presence of synchronous and metachronous lesions. An example is provided by examining the pedigree of one of the families in the data base of the current study (Fig. 3). Let us assume that the surgeon is asked to see the patient indicated by the box. He is a 46-year-old man with a newly diagnosed colon cancer. He has a past medical history of two previous colon cancers, one at age 37 and another at age 43. Inquiry concerning his family history reveals that his father and his paternal grandfather both had colon cancer. In addition, colon cancer has developed in three aunts and one uncle on his father's side. Finally, two of his paternal cousins have been affected. The autosomal dominant inheritance pattern is obvious. More detailed questioning will confirm the presence of frequent metachronous lesions, relatively early age of onset, and a proclivity for proximal colon involvement. No other measures are necessary to confirm that this patient is a member of an HNPCC kindred.

Figure 3 also illustrates another important consideration in evaluating patients for the presence of HNPCC. The family is an example of Lynch Syndrome II, which is determined by the inheritance of the endometrial cancer in concert with the colon cancer. Endometrial cancer developed in the patient's aunt (see arrow Fig. 3) at age 45. The chance of this being a random event is small because the incidence of endometrial cancer in the general population is only 3.6%.[1] This, coupled with her relatively young age for the development of endometrial cancer, makes it likely that she harbors the deleterious gene that contains both cancers. Thus, she is at great risk for the development of colon cancer if she lives long enough. It is simply a matter of the endometrial cancer phenotype being expressed before the colonic. For the same reasons, the patient's niece, who developed colon cancer at age 39, is at great risk for endometrial cancer.

Therapy of HNPCC

Treatment considerations for patients who are members of HNPCC kindreds should be divided into three clinical situations: (1) treatment of the patient with a newly diagnosed colon cancer, (2) recommendations for family members as yet unaffected by colon cancer, and (3) recommendations for patients who have had a previous conventional colectomy that is now known to have been inadequate therapy because the HNPCC syndrome has just been identified (see Table 3).

Treatment of a Newly Diagnosed Colon Cancer Patient

On the basis of our data on synchronous and metachronous colon cancer, we recommend a subtotal co-

TABLE 3. *Summary of the Treatment and Surveillance Recommendations for an Individual Known to be a Member of an HNPCC Family*

I. A patient with a newly diagnosed colon cancer:
  (1) Lynch I and II patients:
    A. Subtotal colectomy with ileorectal anastomosis.
    B. Biannual endoscopic evaluation of the remaining rectum.
  (2) Lynch II patients only:
    A. Female genital tract cancers: consider prophylactic TAHBSO at the time of the colectomy. Otherwise, biannual pelvic examination and yearly endometrial aspiration biopsy. ? Ovarian ultrasound.
    B. Individualized surveillance program as determined by the pedigree if the extracolonic cancer is also extragenital.
II. A patient as yet unaffected by cancer:
  (1) Lynch I and II patients:
    A. Biannual occult fecal blood testing beginning at age 20.
    B. Yearly colonoscopy beginning 5 years earlier than the age of onset of the earliest colon cancer in the family.
    C. Prophylactic subtotal colectomy with ileorectal anastomosis for obligate gene carriers.* Biannual endoscopic evaluation of the remaining rectum.
  (2) Lynch II patients only:
    A. Female genital tract cancers: biannual pelvic examination and yearly endometrial aspiration biopsy. ? Ovarian ultrasound.
    B. Individualized surveillance program as determined by the pedigree if the extracolonic cancer is also extragenital.
III. A patient treated by partial colectomy before being recognized as an HNPCC family member:
  (1) Lynch I and II patients:
    A. Biannual occult fecal blood testing.
    B. Yearly colonoscopy.
    C. A completion subtotal colectomy if not totally compliant.*
  (2) Lynch II patients only:
    A. Female genital tract cancers: biannual pelvic examination and yearly endometrial aspiration biopsy. ? Ovarian ultrasound.
    B. Individualized surveillance program as determined by the pedigree if the extracolonic cancer is also extragenital.

* An opinion from a clinical geneticist is urged before proceeding with therapy.

lectomy with ileorectal anastomosis. Because of the propensity of these cancers to involve the proximal colon, sacrifice of the rectum would not be routinely performed. Even the less mutilating mucosal proctectomy, pouch-anal procedures are not believed to be indicated because the incidence of rectal cancer does not justify the added morbidity when compared with ileorectal anastomosis.[8] Of some concern, however, is the concept that by transferring the effluent of the distal ileum from the right colon to the rectum, one might establish the same environment in the genetically susceptible mucosa of the rectum that had previously existed in the right colon. This could result in a high incidence of cancer in the retained rectum.[9] As yet, no data are available to address this question because so few patients are treated correctly with a subtotal colectomy when the initial colon cancer is diagnosed. Since the majority of patients we are now following for HNPCC are being treated with a subtotal colectomy at diagnosis of the first colon cancer, mature data should be available in several years.[10] Currently, frequent endoscopic evaluation of the remaining rectum is all that is recommended.

Patients from Lynch Syndrome II families must also have consideration given to integrally inherited extracolonic cancers. In this study, all of these cancers involved the female genital tract. Therefore, hysterectomy and bilateral salpingo-oophorectomy is recommended at the time of the colectomy. A difficult problem exists in the younger patient, perhaps in her early 30s. Factors such as childbearing desires, osteoporosis, psychological considerations, and the carcinogenic effects of prolonged estrogen replacement therapy complicate the management recommendations. A decision concerning removal of these organs must be individualized for each patient. If hysterectomy and oophorectomy are not performed, a screening program consisting of biannual pelvic examinations with attention to the ovaries and yearly endometrial suction curettage as an office procedure should be begun. The role of screening ovarian ultrasound is currently under investigation.[11]

If the extracolonic cancer is also extragenital, the pedigree must be examined on an individual basis and recommendations made to the family concerning risk. Prophylactic treatment of these organs is usually not practical but an effective surveillance program should be outlined. An opinion from a geneticist in these uncommon families may be in their best interest.

Recommendations for Other Members of the Family as Yet Unaffected by Colon Cancer

The autosomal dominant inheritance pattern of this condition dictates that only 50% of the first-degree relatives in an HNPCC kindred have the cancer gene. In general, prophylactic colectomy is not recommended. It is imperative that an effective surveillance program be established. Our recommendations include biannual fecal occult blood testing and yearly colonoscopy beginning 5 years earlier than the youngest colon cancer occurring in the family, *i.e.*, age 25–30. It is our belief that yearly endoscopy is mandatory because the widely accepted polyp cancer sequence in sporadic cancer may not be applicable to this hereditary cancer syndrome. So called "flat mucosal" cancers have been suggested by patients who have had thorough colon examinations, both operatively and endoscopically, only to present with invasive colon cancer in a period of just a few months.[2]

There are some situations in which the risk for developing cancer approaches 100% and therefore prophylactic surgery is indicated. An example would be a patient from an HNPCC family who relates a history of a parent and a son or daughter who has developed colon cancer. Mendelian genetics dictates that an autosomal dominant gene could not have been passed from the parent to a grandson or granddaughter without being present in the "middle" person (obligate gene carrier). This assumes that the gene was not present in the opposite side of the family and that the development of colon cancer in the parent, grandson, or granddaughter was not a random event. Since the gene has a high degree of penetrance (89%), the risk of developing colon cancer is extremely high.[10] Prophylactic subtotal colectomy with ileorectal anastomosis is recommended in this situation.

In Lynch Syndrome II patients, a surveillance program must also be outlined for selected extracolonic cancer as determined by the individual pedigree. For families with integrally inherited female genital tract cancer, we are currently recommending biannual pelvic examinations and yearly endometrial suction biopsies beginning at the same age as the endoscopy.

Recommendations for Those Individuals Affected by Colon Cancer but Treated before being Recognized as a Member of an HNPCC Family

It is not unusual to see a patient who has had a conventional partial resection for colon cancer in which the significance of the family history was not appreciated. Our data suggest that the risk of developing metachronous colon cancer is 40% by 10 years. At the very least, an aggressive screening program for the remaining colon and the appropriate extracolonic organ(s) (Lynch Syndrome II patients only) must be recommended. Examination of an individual pedigree sometimes discloses a higher rate of metachronous colon cancer than average. In these patients we recommend conversion to subtotal colectomy. This recommendation is also made in any patient who will not be totally compliant with an effective surveillance program.

Conclusion

Construction of a nuclear pedigree in patients with colon cancer allows the use of basic genetic principles to ascertain an autosomal dominant inheritance pattern. HNPCC is confirmed when the autosomal dominant inheritance pattern is found to be coincident with the cardinal clinical features for the colon cancer, namely, early age of onset, proximal involvement, and frequent synchronous and metachronous lesions. Subtotal colectomy with ileorectal anastomosis is the treatment of choice for a patient with a newly diagnosed colon cancer who is a member of an HNPCC kindred. Extracolonic adenocarcinomas are common in some of these families (Lynch Syndrome II), and thereby dictate the need for prophylactic extirpative surgery or at least an intensive surveillance program directed at the specific organs suggested by the pedigree. Members of the kindred who are as yet unaffected by cancer are at a 50% or greater risk, (*i.e.*, obligate gene carriers approach 100% risk). An intensive surveillance program is begun at a young age. Prophylactic surgery is recommended in selective cases. Finally, patients treated for colon cancer with a partial colectomy before it was discovered that they were members of an HNPCC kindred should have their follow-up treatment considered in the light of a 40% chance of metachronous colon cancer developing by 10 years. These treatment recommendations are summarized in Table 3.

Discussion

DR. CLAUDE H. ORGAN, JR. (Oklahoma City, Oklahoma): I rise to congratulate Dr. Fitzgibbons and his associates for identifying a distinctive subset of colonic neoplasms that have as their characteristics an early age of onset, an autosomal dominant mode of transmission, an excess proximal concentration of these lesions, increasing numbers of synchronous and metachronous lesions, and the possibility of an improved survival.

C. P. Snow has suggested that we are suffering from two coexistent but inadequately communicating cultures: the culture of the clinician and the culture of the basic science investigator (JAMA 1973; 225:617–621).

What is clearly needed for the most effective translation from discovery to practice is not only better communication but a happy cohabitation. Familial colon cancer interfaces both basic science and clinical medicine and offers a method of communication and cohabitation.

A genetic factor has been repeatedly suggested as part of the etiology of colon cancer despite the persistent criticism that such cancer clusters were chance occurrences or the result of shared environmental and dietary influences.

(Slide) This slide confirms the reported kindred manifest in site-specific colon cancer in the absence of familial polyposis dating back to 1956.

I apologize for this being such an active slide, but these are 11 worldwide reports. If you look at the bottom line, you will notice that between 40 and 70% of these cancers are located in the proximal colon (with an average of 67%) and the mean age at onset varies from 29 to 51 years in these 11 worldwide reports with a mean average of 40 years of age. In a majority of instances in which the primary was in the left colon, the metachronous or the synchronous carcinoma was in the cecum.

Dr. Fitzgibbons has appropriately brought to our attention the genetic heterogenicity of these lesions, which is important in the follow-up and subsequent evaluation of these individuals for a long period.

The data he has presented in this paper justify the use of total colectomy with rectal preservation in those cases in which the pedigree analysis and the pathology confirms the presence of hereditary nonpolyposis colonic cancer. These findings must be viewed with the realization that colonic cancer is the most common visceral cancer in the United States.

The development of extended pedigree analysis with tumor and genealogic verification is a long-term, ongoing, dynamic process. Dr. Lynch and his colleagues have shown, with a tenacious group of nurses and social workers, that it is possible to upgrade these pedigree analyses each year.

The observations contained in this report from the familial control center must be viewed cautiously pending the evaluation of much larger cohorts of familial colon cancer with matched controlled individuals inflicted by sporadic colon cancer.

Future epidemiologic surveys of the American Cancer Society's Cancer Commission would be wise to include the familial history in the data base.

I have two questions: (1) are you comfortable using the term "hereditary" in this group of patients since we have not as yet established a single gene-determined etiology, and (2) could this shift from the left to the right side be a national trend as pointed out by Dr. Morgenstern and others?

DR. JEROME J. DECOSSE (New York, New York): Perhaps it should be noted that the concept of subtotal colectomy is not a new one, for it was described by Wangensteen and Lillehei about 1952, then in the context of an isolated large bowel cancer plus additional adenomas present throughout the large bowel.

I would like to interject a word of caution in this regard, perhaps in a few questions to the authors.

I note that they have described over four generations in their pedigrees. That may take them back 100 years. In our experience with this it is difficult to achieve the certainty in records which appears to be required in the diagnoses given in this paper. Could you tell us how you achieve this kind of accuracy?

Secondly, would the author elaborate on the distinctions between familial *versus* hereditary colon cancer, and how this distinction is made, particularly in relationship to the presence or absence of large bowel adenomas, which seems to be a marker for higher risk.

Finally, the author made a statement that colon cancer and endometrial cancer are on the same gene, perhaps because they seemed to segregate together. Does the author have other evidence that this is the case for that is a major statement?

DR. MALCOLM C. VEIDENHEIMER (Burlington, Massachusetts): Like many surgeons, we have performed total abdominal colectomies for cancer of the colon developing in patients under the age of 50. Probably we have been dealing with this subset of patients described in this current paper without fully understanding that we were so doing.

Under normal circumstances, about one third of all specimens removed for cancer of the colon have associated polyp disease in the resected specimen. Like Dr. DeCosse, I ask whether there was such an incidence of associated polypoid disease in the patients described in this paper.

I would like also to caution against the reliance on Hemoccult® testing in this high risk group. Polypoid disease is notorious for not producing occult blood when Hemoccult® testing is performed. I believe that this high risk group should be placed into a surveillance program that mandates colonoscopy unless they already have had a total colectomy and ileorectal anastomosis.

DR. JOHN S. SPRATT (Louisville, Kentucky): I have one comment, and I would like to ask the authors two questions.

The comment is that the left to right shift can be traced to the mid-1960s when double contrast enema and colonoscope became available. In the autopsy studies that antedated that period there were always many neoplasms in the right colon.

Secondly, in Dr. Lynch's group, there was an author of several papers named Albano many years ago whom I unfortunately never met, but he published one very good paper that said that the cancers associated with this syndrome had a much better prognosis. I would like to know if that is still true.

The second question is: does the vigorous follow-up system that they have suggested show any reduction in the chance of dying of colon cancer?

DR. ROBERT J. FITZGIBBONS, JR. (Closing discussion): Dr. Organ, I very much appreciated your comments, especially because I know of your sustained interest in this subject. You asked if we were noting a shift from a left to a right dominance of colonic cancer in these patients. These cancers tend to be confined to the right colon. We have looked at this carefully because in the general population, it is left-sided. Right-sided colon cancer predominance is integral to criteria for HNPCC.

Dr. DeCosse, you cautioned us about the danger of ascribing this to a single gene without biochemical evidence. We are basing our conclusion of a single autosomal dominant gene on extensive medicogenetic investigations by our group and by colleagues throughout the world. In addition, formal segregation analysis (Bailey-Wilson, et al. Genetic Epidemiology 1986; 3:27–38.) has fully supported this assumption. We very much appreciate the fact that there is no biochemical justification. We are currently investigating the molecular basis for this problem.

Dr. Veidenheimer and Dr. DeCosse both asked: what is the relationship of polyps in this syndrome? There are adenomatous polyps associated with this condition occasionally. However, we have been impressed that patients whom we have been following closely in our Hereditary Cancer Institute show a paucity of adenomatous polyps. We believe that the cancer–polyp sequence seen in sporadic colon cancer is not always active in HNPCC and that some of the colonic cancer in the Lynch syndromes are the result of so-called flat mucosal lesions.

Dr. DeCosse asked that I define the difference between familial and hereditary colon cancer. Familial colon cancer includes those families in which two or more first degree relatives have been afflicted with colon cancer, but without a clear-cut vertical transmission pattern consonant with an autosomally dominant inherited factor. In addition, these families do not show early age at onset, multiple primary colonic cancers with increased synchronous and metachronous lesions, or an excess of female genital cancers, as in Lynch syndrome II. Hereditary colon cancer families, on the other hand, show these features, which are striking in our own extended kindreds.

You also asked about how we were able to thoroughly document these 10 families. As Dr. Organ mentioned, we do have an extremely aggressive staff that looks very carefully at these people. In Nebraska, we have the advantage of having a fairly stable population with minimal migration. Documentation has taken place through very thorough review of medical records, autopsy reports, pathological reports, and operative notes on the vast majority of our cases.

Dr. Spratt, you mentioned my late colleague Dr. Bill Albano. Yes, we are indeed still seeing the better prognosis in these patients that he reported when he published his paper. Clearly, these hereditary nonpolyposis colon cancers for some reason have a better prognosis, but the basis for this remains elusive.

Regression of Atherosclerosis by the Intravenous Infusion of Specific Biochemical Nutrient Substrates in Animals and Humans

STANLEY J. DUDRICK, M.D., F.A.C.S.*

Preliminary studies in 400 New Zealand albino rabbits produced a reliable animal model of nutrient-induced atherosclerosis that simulated that observed in humans. Atherosclerosis was then induced in an additional 1600 rabbits in sets of 40 animals each, maintaining plasma cholesterol concentrations between 1000 and 2000 mg/dL for 6–20 weeks. In each set, 10 control rabbits were killed to document baseline atherosclerosis, and the other 30 rabbits were assigned randomly to one of three groups of 10 rabbits. Groups of 10 rabbits were either continued on the atherogenic diet (group I), given standard laboratory rabbit pellets (group II), or infused continuously with specially formulated anticholesterol solutions *via* central venous catheters (group III) for 6 weeks. At autopsy, atherosclerotic lesions consistently involved 85–95% of the aorta in group I. In group II, atherosclerosis was comparable with the baseline control group with no regression. In group III, regression of atherosclerosis by 90–95% was consistently documented. Correlations between plasma amino acids and plasma cholesterol concentrations were established in four humans with severe atherosclerosis to maximize the cholesterol reduction capacity of the amino acid formulation. Infusion of the modified total parenteral nutrition solution induced prompt reduction in plasma cholesterol levels by 40–60% regardless of the initial level and was accompanied by evidence of regression of atherosclerosis after a 90-day infusion therapy period.

From the Department of Surgery, The University of Texas Medical School at Houston, Hermann Hospital, Houston, Texas

THE ROLE OF CHOLESTEROL in the etiology and pathogenesis of atherosclerosis has been debated by clinicians and investigators for many decades.[1] An elevated plasma cholesterol concentration is certainly not the only cause of, or contributing factor to, coronary heart disease. However, it appears that reducing elevated plasma cholesterol levels will decrease the risk, or is associated with a decreased risk of myocardial infarction secondary to atherosclerotic coronary heart disease.[2,3]

During the past 20 years, as clinical applications of total parenteral nutrition (TPN) have been expanded, it has been documented that plasma cholesterol concentrations decline to low or low normal levels especially in puppies, infants, critically ill malnourished adults, and long-term home TPN patients. However, early attempts to correlate short-term TPN-induced hypocholesterolemia with regression of peripheral vascular disease by our team at the Hospital of the University of Pennsylvania in six patients studied for 1 month were unsuccessful. Subsequently, several patients in our series who had mesenteric infarction of the small bowel secondary to severe atherosclerosis required another abdominal operation after 3–5 years of nourishment entirely by vein. In four of these patients, the previously documented atherosclerosis in the major abdominal vessels had decreased dramatically or was undetectable at intraoperative evaluation. In six such patients in their fifth to eighth decades of life who died for reasons unrelated to their cardiovascular system after 3.5–15 years of home TPN, postmortem examination demonstrated minimal atherosclerosis or disease-free vessels.

Foremost among other workers who observed cholesterol lowering effects of fat-free TPN were Starzl et al.,[4,5] Folkman et al.,[6] and Yamashita et al.[7] who made novel clinical applications of this phenomenon to the management of patients with hyperlipoproteinemia, glycogen storage disease, and familial hypercholesterolemia.

The goals of this series of investigations were to: (1) strictly control nutrient substrate administration in rabbits and humans to determine the maximum dietary potential to reduce plasma cholesterol concentrations while maintaining adequate nutrition; (2) modify existing intravenous nutrient substrate mixtures to maximize

their cholesterol reducing effects; (3) determine whether these diets, either directly or secondary to induced hypocholesterolemia, could arrest and/or induce regression of atherosclerosis; and (4) determine whether improved cardiovascular function and secondarily improved blood flow to vital tissues would thereby result.

Animal Studies

Preliminary laboratory investigations were done in 400 New Zealand albino rabbits to develop a reliable animal model of dietary-induced atherosclerosis. By systematically altering the fat, cholesterol, and fiber in the oral diet, a special formulation evolved that consistently induced atherosclerotic lesions comparable in composition, distribution, and gross and histologic appearance to those commonly occurring in humans. The atherogenic rabbit diet (Table 1) was subsequently fed to an additional 1600 animals in quantities sufficient to maintain plasma cholesterol levels at approximately 1000 mg/dL without untoward hepatobiliary or gastrointestinal complications. The severity of atherosclerosis in the major vasculature could be estimated by observing the appearance and extent of atheromatous deposits in the blood vessels of the iris. After 6–20 weeks of maintaining hypercholesterolemia, significant atherosclerosis was routinely demonstrated to affect 30–90% of the surface area of the great vessels, respectively; the lesions were histologically indistinguishable from those seen in humans (Figs. 1–3). By 6 months, some animals had myocardial infarctions, strokes, mesenteric vascular occlusions, and peripheral vascular occlusions secondary to severe atherosclerosis involving more than 95% of the surface of the great vessels and major tributaries.

A large series of experiments was done in sets of 40 rabbits in which plasma cholesterol levels were maintained at approximately 1000 mg/dL in all animals for 4.5 months. Ten animals in each group were killed to determine the gross and histologic extent and character of the atherosclerosis, and the remaining animals in each experiment were assigned randomly to one of three groups of 10 animals each. For the next 6 weeks, group I rabbits continued to be fed the atherogenic diet, group II rabbits were fed standard laboratory rabbit pellets, and

group III rabbits were fed by continuous central venous infusions either with one of the six commercially available amino acid solutions listed in Table 2 or with specially formulated solutions designed to achieve a maximum plasma cholesterol lowering effect. All amino acid mixtures were administered continuously by pump over 24 hours together with all essential vitamins, minerals, and trace elements and all nonprotein caloric requirements as dextrose. All intravenous solutions were fat free. Blood samples were obtained weekly throughout the 6 months to monitor lipid profiles and standard biochemical and hematologic indices. Serum and urine amino acid profiles were obtained monthly, and all animals had autopsies at the end of the study.

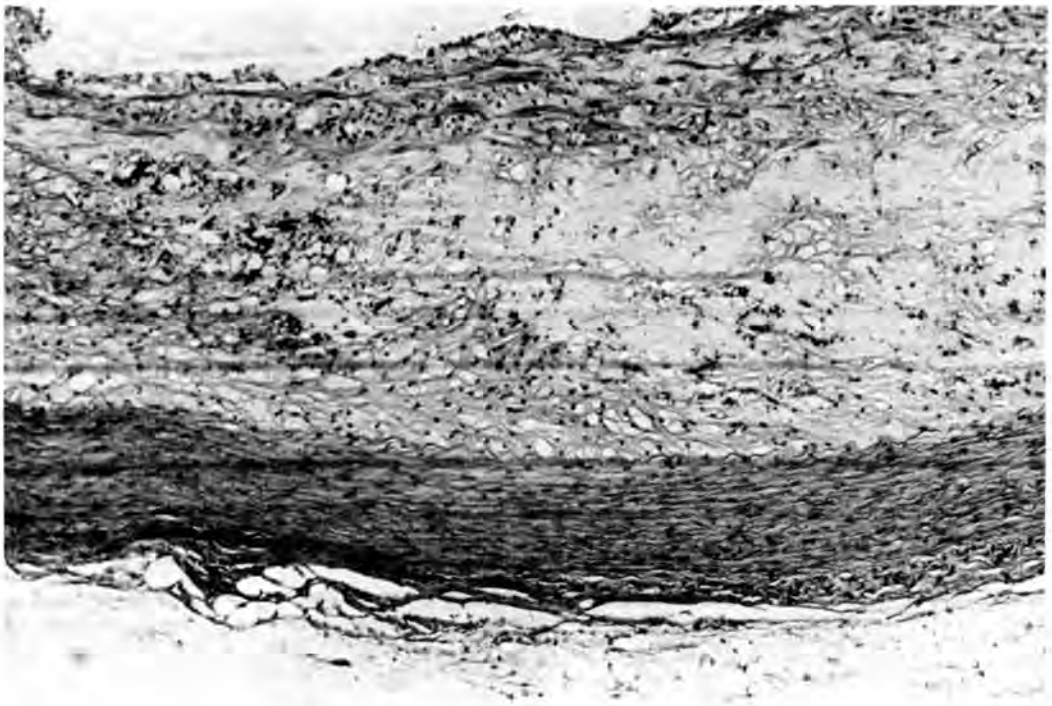

FIG. 2. Low power longitudinal section of the aorta from an animal fed a high-cholesterol diet for 4.5 months. The intima histologically fulfills the criteria of a complicated lesion with: (1) smooth muscle proliferation and expansion of the intima from 1 to 30 cells thick, (2) focal calcification is depicted by the darkly stained calcium deposits, (3) vacuolated appearance of foam cells, and (4) extracellular deposits of cholesterol as cholesterol clefts.

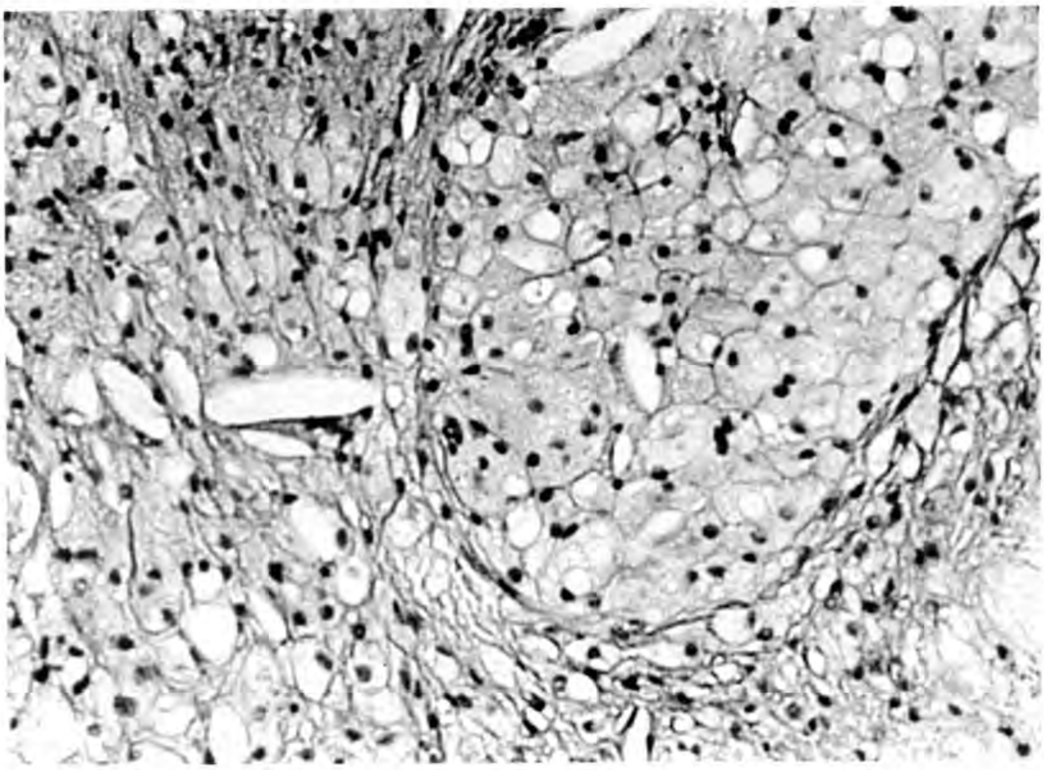

FIG. 3. This high power photomicrograph depicts the deposition of cholesterol and fats both intracellularly (foam cells) and extracellularly (cholesterol clefts).

In group I animals, complex atherosclerotic lesions consistently involved 85–95% of the great vessels. In group II animals, the atherosclerosis was comparable with that in the 4.5-month atherogenic control group with no evidence of significant progression or regression. In group III animals, significant regression of the atherosclerosis was consistently documented by 90–95% clearing of the surface area of the great vessels and major tributaries (Figs. 4–8).

In the first six sets of 40 rabbits, the group III animals received one of six commercially available amino acid solutions (Table 2). After the 6-week intravenous infusion period using these solutions, regression of atherosclerotic lesions varied from minimally detectable to

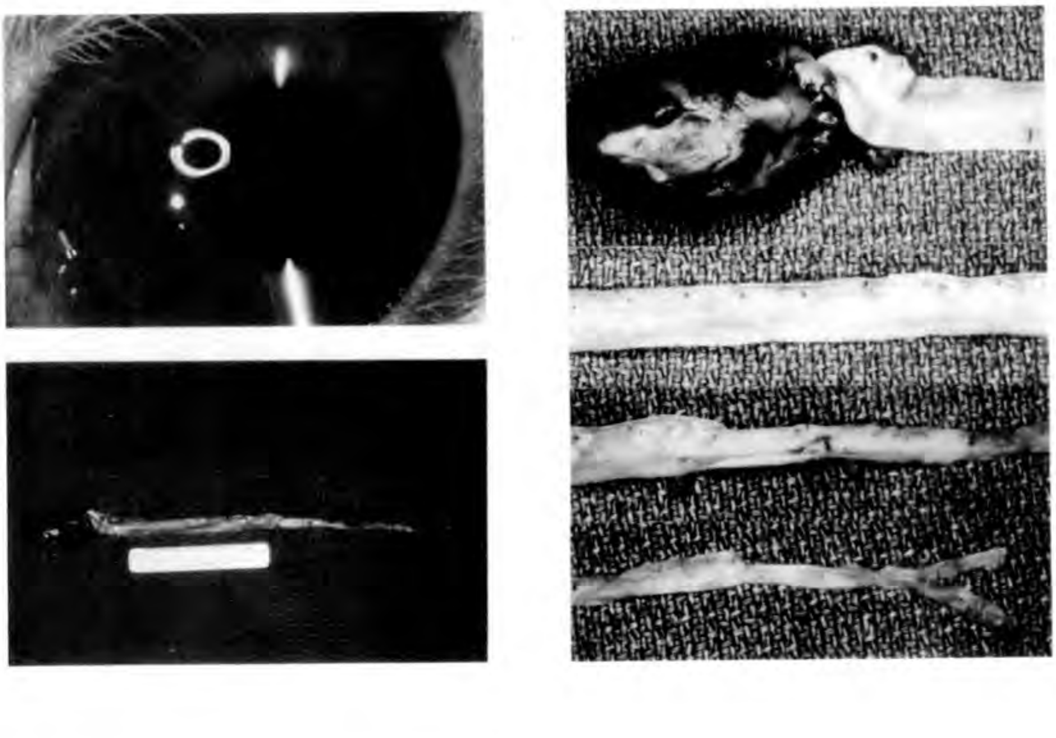

FIG. 4. Composite picture depicting a normal rabbit iris and intimal surface of the aorta with no evidence of atherosclerosis.

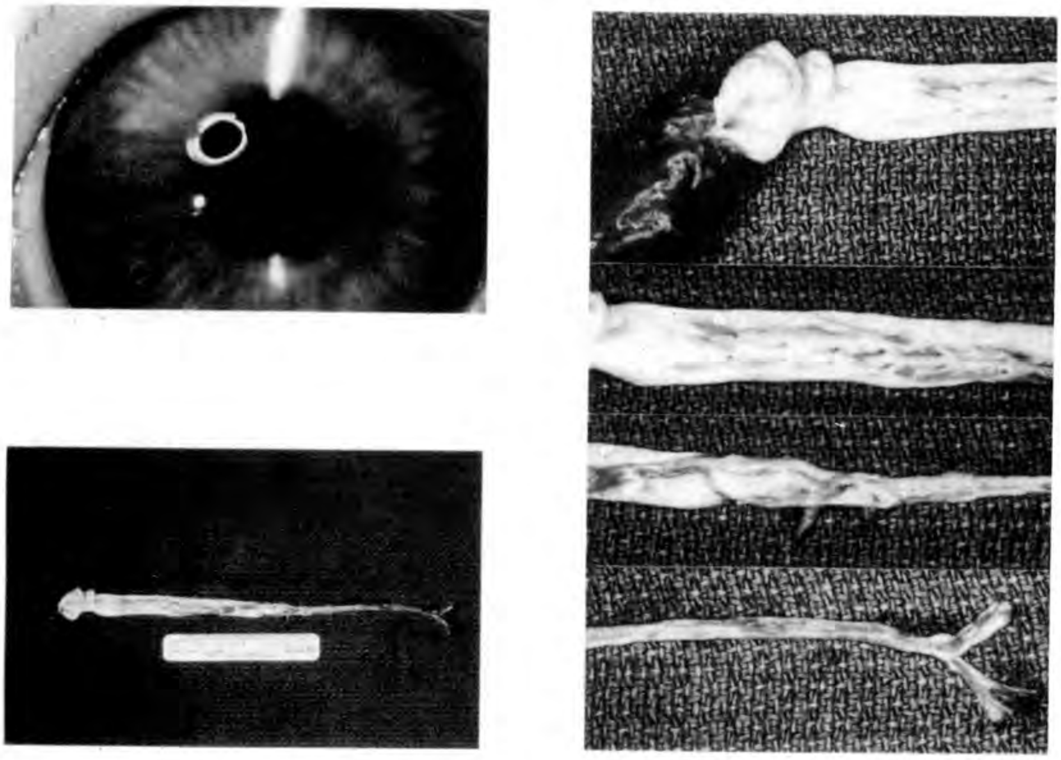

FIG. 5. Composite picture of the iris and aorta in a rabbit fed the high-cholesterol diet for 4.5 months. The lack of pigment in the iris allows direct visualization of the deposition of plaque in the vascular bed, which correlates positively with the atherosclerosis involving 90% of the aorta.

5–10% regression. By correlating plasma and urine amino acid concentrations with plasma cholesterol levels in these animals, changes in the percentages of the individual amino acids were made sequentially in the group III animals and all subsequent sets of rabbits. As a result of these manipulations, a 9.5% amino acid formulation evolved that induced 90–95% regression of the dietary-induced atherosclerosis within 6 weeks. The

bits that were fed the atherogenic diet for 6 months and then fed the standard laboratory rabbit pellets for up to 2 years.

Patient Studies

Pilot Study: Case 1

A 40-year-old white man with Type IIB hyperlipidemia had an acute anterior myocardial infarction at age 32. After recovery, he was treated with clofibrate, Questran®, and Coumadin®. His plasma cholesterol levels ranged between 500 and 800 mg/dL and his serum triglyceride levels ranged from 800–1000 mg/dL. Dietary manipulation begun in 1977 maintained his plasma cholesterol to levels between 450 and 560 mg/dL. Cardiac catheterization in April 1984, showed 100% occlusion of his right coronary artery and diffuse atherosclerotic disease involving the left anterior descending and circumflex coronary arteries.

Due to the development of progressively increasing severity and frequency of angina pectoris, severe claudication after walking one block, daily dizziness and syncope, and episodic numbness in his extremities related to poor and/or absent pulses in his neck, arms, and legs, he agreed to undergo a 6-month period of intravenous anticholesterol therapy beginning in May 1985. A percutaneous subclavian central venous feeding catheter was inserted into the patient's superior vena cava, and a continuous infusion of the modified TPN solution that had ultimately evolved during the rabbit studies was begun after obtaining baseline biochemical and hematologic studies and instructing the patient in the basic principles and practices of ambulatory home TPN. The patient was allowed absolutely no food by mouth but could drink water *ad libitum*. The patient received no fat during the study, and all nonprotein caloric requirements were provided as dextrose. Since he was approximately eight pounds above his calculated ideal body weight, his formulation for the first few weeks was hypocaloric until he achieved his ideal body weight. Essential vitamins, minerals, and trace elements were provided in accordance with standard home TPN practices. Within 10 days of receiving the initial intravenous anticholesterol diet, his plasma cholesterol level dropped from his preinfusion baseline concentration of 508 mg/dL to 220 mg/dL, representing a greater than 50% reduction. During the 6 months that the patient received the anticholesterol therapy, he had no angina pectoris, dizziness or syncope; his peripheral pulses and perfusion improved greatly; the Doppler blood flow to his left leg increased 250% and to his right leg increased 300%; and the episodic numbness in his hands and feet disappeared completely.

After 4 weeks of therapy, the patient's general health, strength, and feeling of well being improved sufficiently, and he was begun on a graduated monitored treadmill exercise program. During the fifth week of his therapy, he walked 1 mile a day on the treadmill at 1 mile per hour and by the eighth week was walking 3.5–4 miles a day at 3.5 miles per hour without pain or claudication in his legs and with no angina pectoris. During the ninth week of therapy he began to play 18 holes of golf several times a week scoring in the 70s, despite the handicap of having to wear the continuous intravenous infusion apparatus.

During the course of his therapy and study, frequent plasma and urine amino acid concentrations were determined and correlated with his plasma cholesterol level (Fig. 9). At point two, the branched chain amino acids, isoleucine, leucine, and valine, were increased in the formula. At point three, phenylalanine was increased and glycine was decreased in the formula. At point five, alanine was decreased, and glutamic acid and aspartic acid were increased. At point ten, proline and serine were decreased, and at point twelve, arginine was increased, whereas histidine was decreased.

On day 60 at point six, 500 mL of 10% soybean oil emulsion (10% Intralipid, KabiVitrum, Stockholm, Sweden) was infused into the patient over 6 hours, and the plasma cholesterol concentration rose promptly and dramatically more than 100 mg/dL to 365 mg/dL and remained above 300 mg/dL for 1 month. At that point 500 mL of 20% soybean oil emulsion (20% Intralipid, KabiVitrum) was infused over 6 hours, and the plasma cholesterol level again rose significantly but not as high nor as persistently as the initial infusion of the 10% soybean oil infusion. However, the persistent adverse effects on plasma cholesterol levels after infusions of such relatively small amounts of fat emulsion are obvious, dramatic, and disturbing.

Between days 140 and 150, the plasma concentration of arginine was approximately 100 μmol/L, and the urine concentration of arginine was approximately 40 μmol/L (Fig. 10). Because this represented the lower limit of normal for plasma arginine concentration, the dosage of arginine in the infusion mixture was doubled for the next 10 days. This resulted in a rise in the plasma amino acid concentration of arginine to approximately 200 μmol/L, the usual upper normal limit, whereas urine excretion of arginine increased. Concomitantly, the plasma cholesterol level dropped dramatically from 310 mg/dL to 230 mg/dL. At this point, the arginine dosage in the infusion mixture was tripled with essentially no change in plasma concentration of arginine, a dramatic increase in urinary excretion of arginine, and essentially no change in plasma cholesterol concentration. This sequence of events illustrates the manner in which the dosages of the various amino acids in the anticholesterol formulation were derived. All other numbers in Figure 9 represent changes in dextrose calories in response to changes in the patient's body weight and activity.

The significant changes in plasma apolipoprotein B and triglyceride concentrations are illustrated in Figures 11 and 12.

Coronary angiography after the therapy indicated improved flow in the previously completely blocked right coronary artery and increased diameter and flow in the tributaries of the left coronary artery with the development of increased collateral coronary artery circulation, myocardial perfusion, and cardiac performance (Figs. 13 and 14). Coronary arteriographic analysis using computerized quantitative angiography[8] (Figs. 15 and 16) indicated regression of coronary atherosclerosis by an increase in the diameter in one of the branches of the left coronary artery from 1.19 mm before therapy to 1.30 mm after therapy and an increase in cross-sectional area from 1.12 mm^2 before therapy to 1.27 mm^2 after therapy. Coronary flow reserve increased from 3.6 to 4.2, consistent with the disappearance of his angina pectoris. These data assume even greater potential significance considering that the baseline angiography was performed more than 1 year before the initiation of the anticholesterol therapy and that the patient's continuing symptomatic deterioration during that interval indicated further progression of his coronary atherosclerosis during that year.

To date, the patient is 2 years post-initiation of his anticholesterol therapy and 18 months post-completion of his therapy. He has remained completely free of his initial presenting signs and symptoms, has returned to gainful employment as a Computer Systems Analyst, engages in normal physical activity without limitations, plays golf regularly, and enjoys a feeling of good health and well being.

Home TPN Patients

To determine the extent of the increased effectiveness of the anticholesterol amino acid formulation (Atheromine, Baxter Healthcare Corp., Deerfield, IL) in lowering plasma cholesterol compared with the standard amino acid formulations used in home TPN, 30 patients with short bowel syndrome who had been receiving one of the six commercially available amino acid formulations for 4 months to 9 years were studied. The Atheromine solution that had evolved during the pilot patient

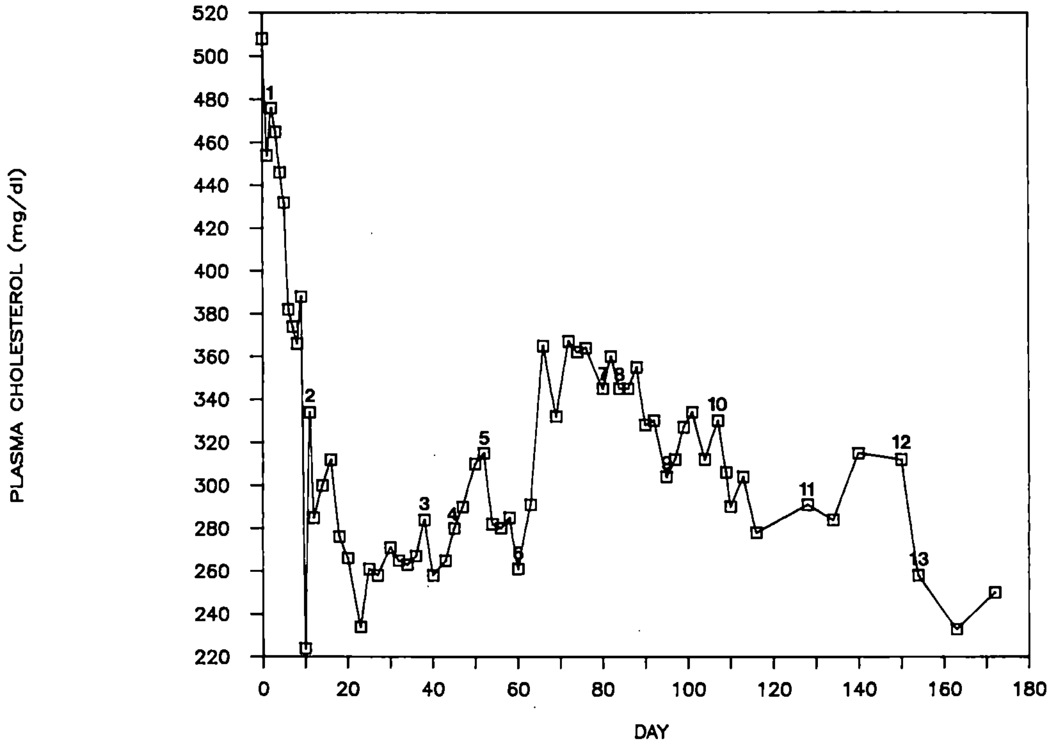

FIG. 9. Plasma cholesterol levels during 6 months of anticholesterol therapy. Numbered points denote significant changes in the components of the formula.

study was substituted for the usual amino acid formula in each of the 30 patient volunteers for 7 days while monitoring plasma cholesterol levels daily. The upper and lower limits of the plasma cholesterol concentrations determined daily for these 30 patients are shown in Figure 17. Prompt reductions in plasma cholesterol

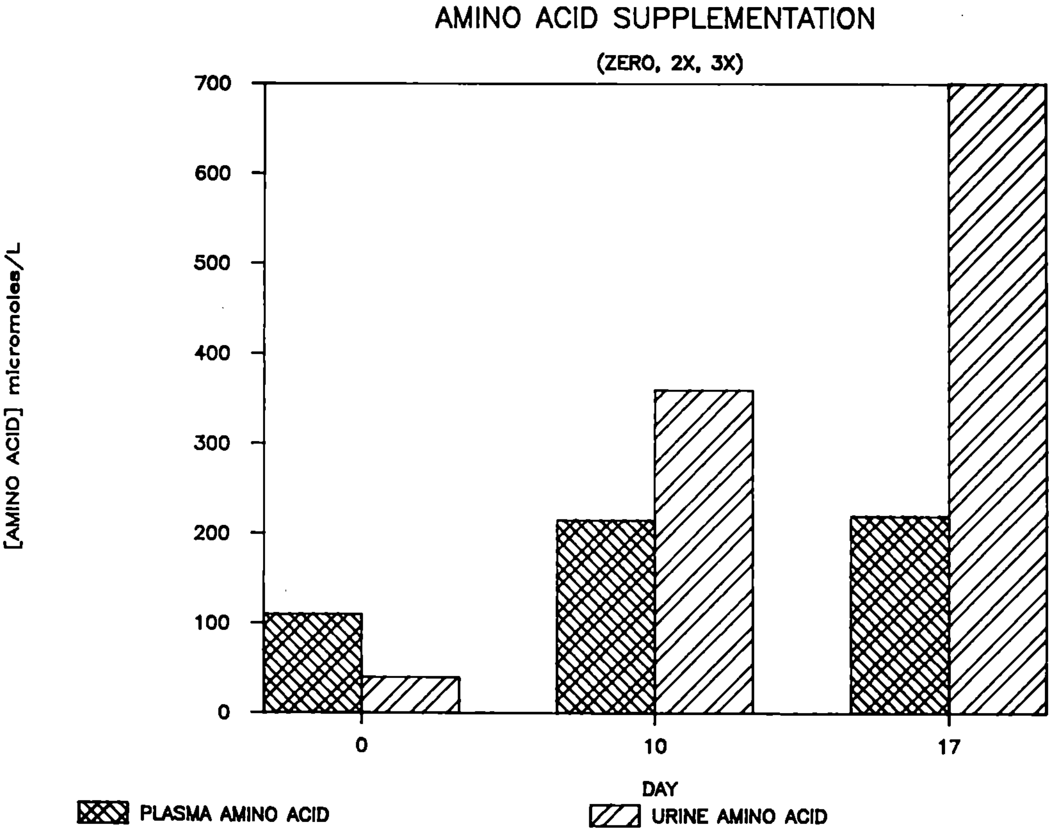

FIG. 10. Relative changes in plasma and urinary arginine levels with changes in the intravenous solution mixture.

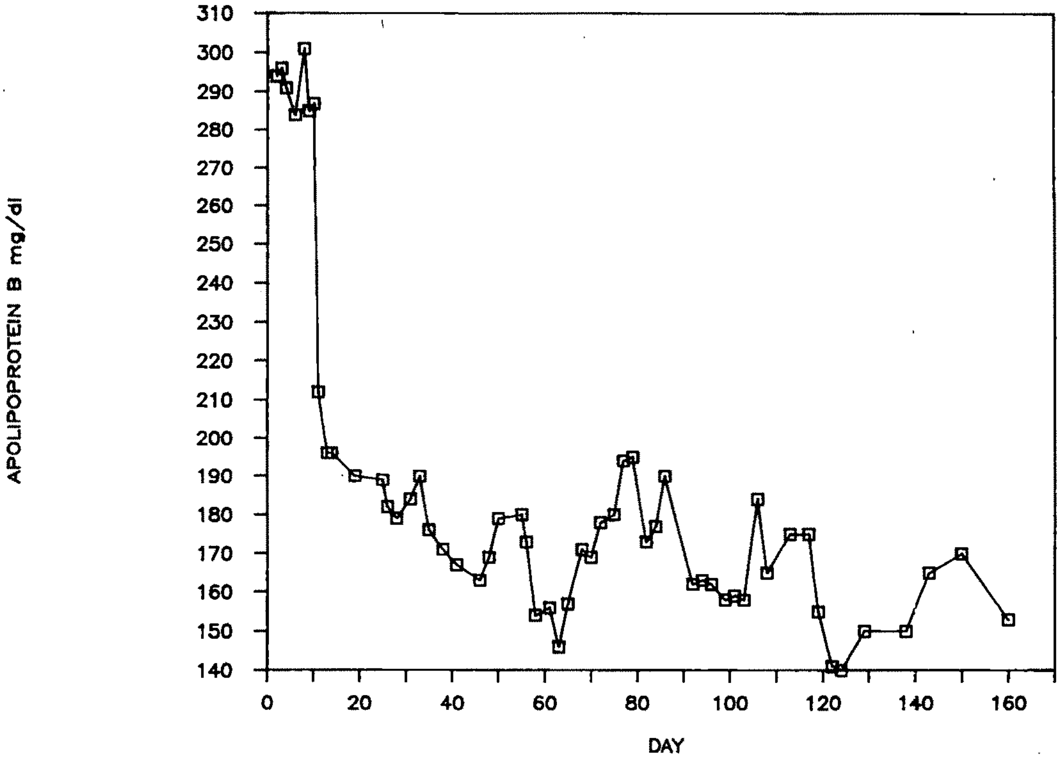

FIG. 11. Alteration of plasma apolipoprotein B levels during 6 months of anticholesterol therapy.

concentrations by 40–60% occurred in all patients regardless of the initial baseline value or the amino acid mixture that had been infused during their standard home TPN regimen. In one patient in whom the baseline cholesterol level was 168 mg/dL, a 58% drop in plasma cholesterol to 70 mg/dL occurred in 7 days.

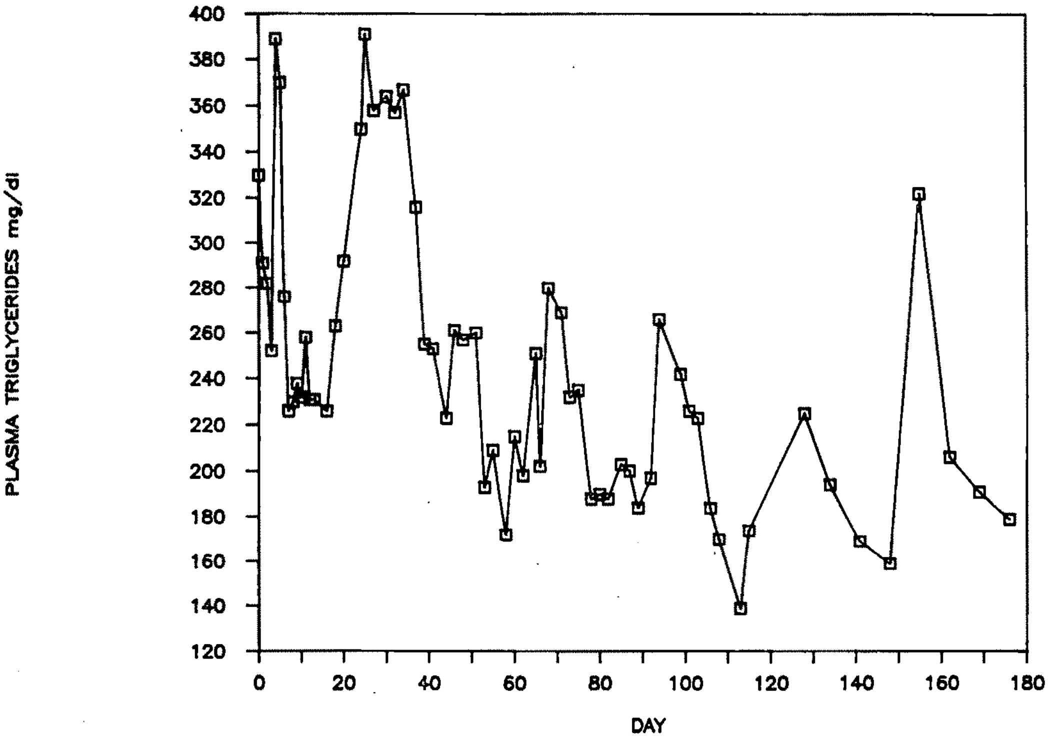

FIG. 12. Alteration of plasma triglyceride levels during 6 months of anticholesterol therapy.

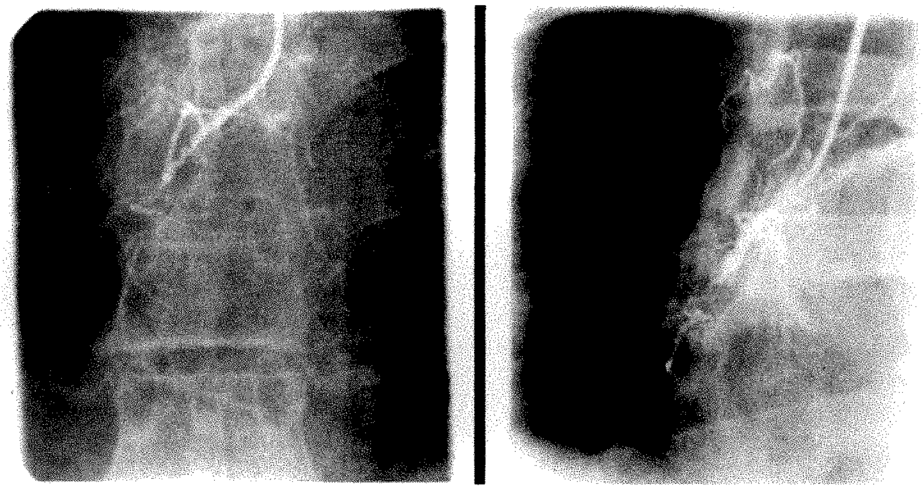

FIG. 13. Angiography shows complete blockage of the right coronary artery before treatment (*left*). Improved flow through the right coronary artery and greatly increased collateral blood flow occurred after therapy (*right*).

Even more dramatic and remarkable was a drop in plasma cholesterol from an already low value of 85 mg/dL by 65% to 30 mg/dL in 7 days.

Case 2

A 55-year-old man with severe coronary artery disease had a myocardial infarction in 1963 at the age of 31. A second myocardial infarction occurred in 1977 and required emergency coronary bypass to five vessels.

Recurrent, persistent angina pectoris developed in March 1985, and in December 1985, he had a third myocardial infarction. Before intravenous anticholesterol therapy, the patient had disabling crushing anterior chest pain 4–5 times per day, even at rest. Cardiac catheterization in 1985 showed three-vessel coronary artery disease with occlusion of the right coronary artery, extensive disease in the left anterior descending coronary artery, occlusion of a large marginal branch of the circumflex coronary artery, and occlusion of all of his bypass grafts with the exception of the left anterior descending graft, which was functioning poorly.

The patient denied angina pectoris after the first two days of anticholesterol therapy with the exception of one mild episode that occurred while riding a bicycle in 30-degree weather against a 45 mph wind for 2.5 miles, a great increase over his usual level of exertional activity.

His medications before anticholesterol therapy included Procardia®, Norpace®, Lanoxin®, Tenormin®, aspirin, nitroglycerin, and nitropaste. At the completion of 90 days of anticholesterol therapy, the patient's only cardiac medication was Lanoxin, and he denied chest pain despite a greatly increased level of physical activity. His initial plasma cholesterol level of 218 mg/dL declined by 39% to a low value during therapy of 123 mg/dL.

His follow-up evaluation included cardiac catheterization and quantitative coronary angiography, which documented an improvement in coronary flow reserve (CFR) from 1.0 to 2.3, an improvement of 130% (Figs. 18–20). Additionally, a pretherapy thallium treadmill test showed a perfusion defect involving the anterolateral, apical, and inferior segment of the left ventricle that did not show any evidence of reperfusion at rest. The post-therapy thallium treadmill test showed resolution of the perfusion defect in the anterolateral segment of the left ventricle. Stress defects and redistribution abnormalities in the apical posterior, lateral, and inferior segments of the left ventricle were not as severe as the pretreatment examination. There was definite evidence for improvement of perfusion of the left ventricle.

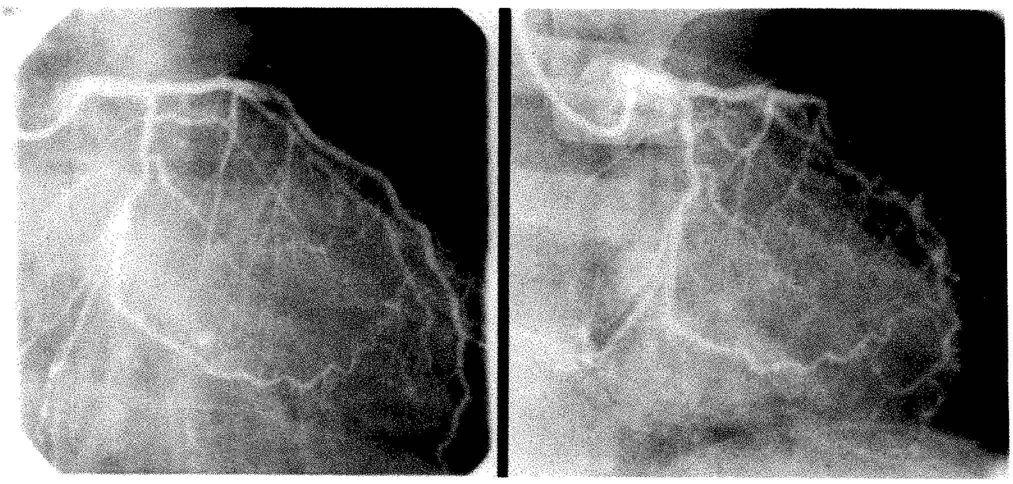

FIG. 14. Increased diameter and blood flow through the left anterior descending and circumflex coronary arteries occurred after therapy (*right*) compared with the pretreatment angiogram (*left*). Improved collateral circulation between the right and left coronary systems can be seen in the left lower quadrant of the right photograph.

FIG. 15. Quantitative coronary angiography showing restricted coronary flow reserve of 3.6 before therapy.

Case 3

A 45-year-old previously healthy white man had an inferior wall myocardial infarction that was complicated by ventricular fibrillation from which he was successfully resuscitated. Cardiac catheterization demonstrated a 50% narrowing of the midlateral anterior descending coronary artery, a 50% narrowing of the circumflex artery, and a normal right coronary artery. Despite treatment with an extremely low-fat, low-cholesterol diet and anticholesterol drugs, including nicotinic acid and cholestyramine, he was unable to decrease his plasma cholesterol level below 250 mg/dL.

FIG. 19. Marked improvement in coronary flow reserve in right coronary artery after 3 months of Atheromine therapy with significantly increased diameter and cross-sectional area of the previously narrowed segment.

angina pectoris in 1971. Cardiac catheterization showed significant coronary artery disease for which he had an internal mammary coronary bypass (Weinberg procedure). In 1980, he had a myocardial infarction, and recurrent and persistent angina pectoris developed in 1981. At that time a second cardiac catheterization documented significant recurrent disease. He had saphenous vein aorta coronary bypass

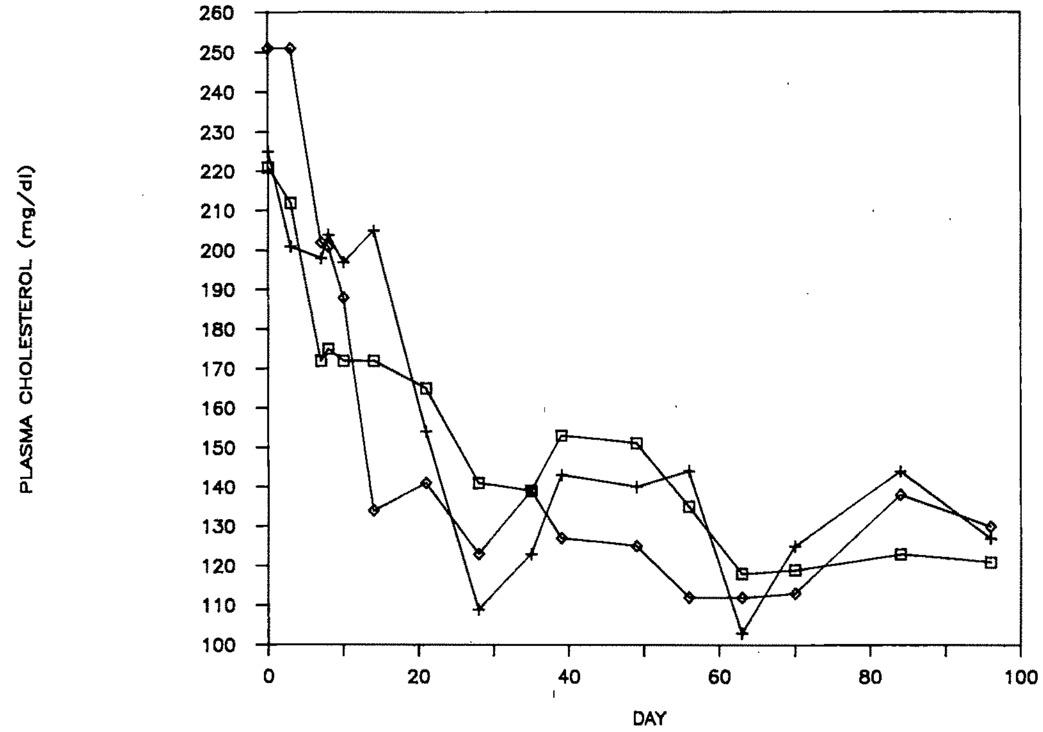

FIG. 21. Total plasma cholesterol levels of three patients during 90 days of Atheromine therapy.

to three vessels with improvement for approximately 2 years until the development of recurrent chest pain primarily associated with exercise. He had cardiac catheterization again in 1983, which showed global hypokinesis with an ejection fraction of 26%, a totally obstructed left anterior descending and distal circumflex coronary artery, and significant disease of the distal right coronary artery.

His angina pectoris became progressively severe over the subsequent 3 years, and at the time of pretreatment evaluation he was having chest pain 4–5 times per day requiring nitroglycerin for relief. He could walk only 2 miles at a slow pace without the development of chest pain. His pretreatment medications included Procardia, Corgard®, and nitroglycerin.

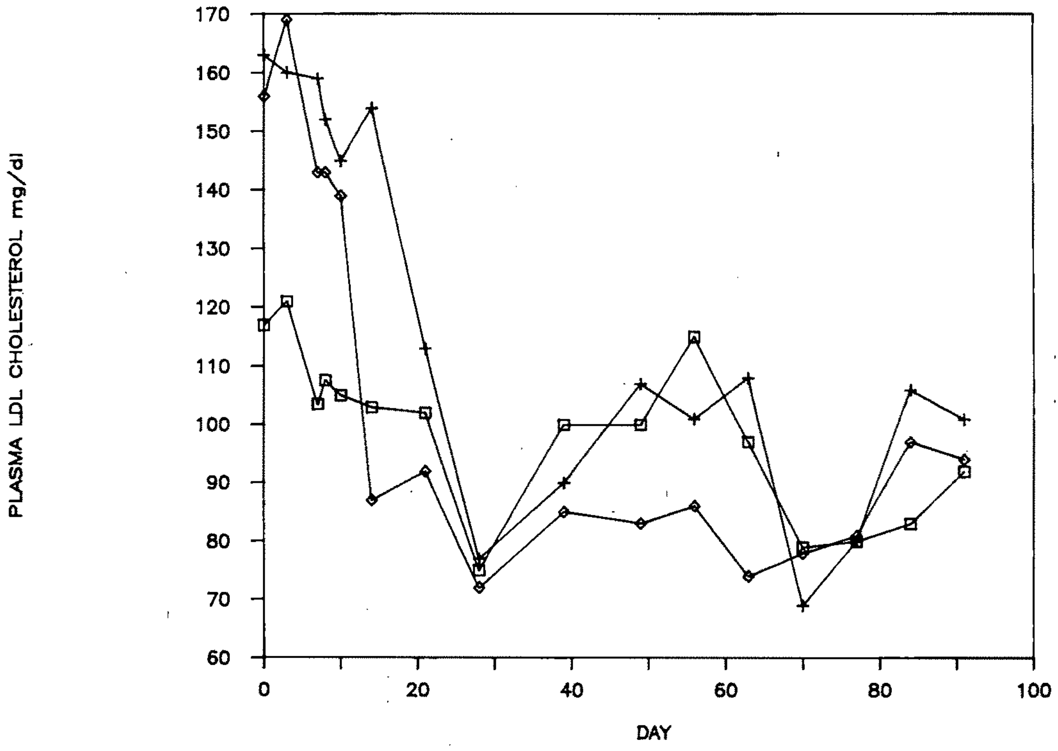

FIG. 22. Plasma VLDL cholesterol levels of three patients during 90 days of Atheromine therapy.

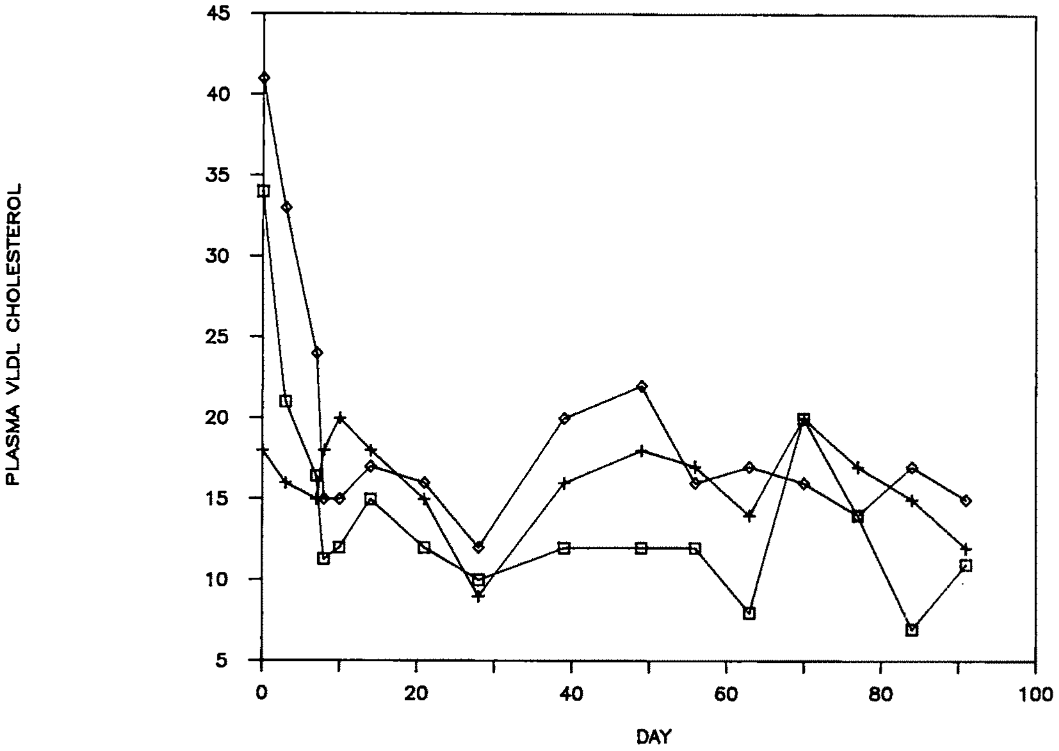

FIG. 23. Plasma LDL cholesterol levels of three patients during 90 days of Atheromine therapy.

After starting anticholesterol therapy, he had no further episodes of angina pectoris despite the development of a subclavian vein thrombosis necessitating placement of a second Hickman catheter and the development of a small bowel obstruction secondary to adhesions that required laparotomy. He lost 16 pounds during the 90-day treatment period and was able to reduce his cardiac medications by 50%.

His initial plasma cholesterol level of 252 mg/dL declined by 66.7% to a low of 84 mg/dL.

His pretreatment positive thallium treadmill test remained positive post-treatment; however, he was able to achieve a 25% higher heart rate during his post-treatment examination. Follow-up cardiac catheterization showed generalized severe coronary atherosclerosis with complete

occlusion of the left anterior descending, circumflex, and right coronary artery and the development of an extensive collateral network with a patent but stenotic vein graft to the right coronary artery and an ineffective left internal mammary graft. His ejection fraction, however, on his post-treatment examination had increased to 55%, representing a 92% improvement.

During and since his therapy he has had no further angina pectoris despite a greatly increased level of activity.

Figures 21–24 are graphic representations of the plasma concentrations of total cholesterol, LDL cholesterol, VLDL cholesterol, and HDL cholesterol during the 90-day period of the intravenous anticholesterol therapy in cases 2, 3, and 4.

Anticholesterol Solution Development

The anticholesterol therapy solution (Atheromine) consists of 18 L-amino acids formulated in quantities and ratios that are optimal for reducing plasma cholesterol concentrations in each patient. Starting with the base formula that evolved during the patient pilot study, modifications in the amino acid formulation are made depending on plasma and urine amino acid concentrations determined weekly until stable and then monthly thereafter. Figure 25 demonstrates the positive, negative, and neutral correlations between the individual plasma amino acids and plasma cholesterol concentrations derived from multiple determinations in three patients. Analyzing these data and plasma-to-urine ratios of the individual amino acids, the individual amino acids in the Atheromine can be adjusted to maximize its effectiveness in reducing plasma cholesterol concentrations.

Table 3 illustrates the average daily anticholesterol therapy solution that can be tailored to meet the nutritional needs of the patient while achieving maximum effectiveness in reducing plasma cholesterol concentration. Thus far, all patients have had the therapy on an ambulatory basis using a lightweight, portable, comput-

TABLE 3. *Average Daily Anticholesterol Therapy Solution*

Amino acids 10.31%	1000 mL
Isoleucine	4.0–10.0%
Leucine	5.0–10.0%
Lysine	4.5–6.5%
Methionine	3.5–5.5%
Phenylalanine	4.5–7.5%

erized pump (Pancretec, Inc., San Diego, CA) to guarantee desired infusion rates with maximum safety. No fat has been administered to the patients since the pilot study, and no evidence of biochemical or clinical fatty acid deficiency has been documented thus far. The cholesterol-reducing effects of the solution are greatly compromised by the oral intake of even minute amounts of lipid substrates and negated completely if the solution is infused by tube into the gastrointestinal tract in rabbits or in humans.

Discussion

Although atherosclerosis represents a spectrum of pathophysiology and clinical manifestations and although hypercholesterolemia represents only one of the causative or contributing factors to the development and progression of atherosclerosis, nonetheless a real and finite relationship between the two exists. Based on available epidemiologic studies, it is highly likely that the vast majority of atherosclerosis and its complications could be ameliorated, corrected, or avoided by strict adherence to an optimal diet providing only 100 mg of cholesterol, 20% of total calories as fat consisting of one-third saturated fat, one-third polyunsaturated fat, and one-third monounsaturated fat and a total caloric ration tailored to meet energy needs and maintenance of ideal body weight. However, it will be a major public health undertaking to convince Americans to make the radical changes in their current diets to achieve the optimal target diet outlined. Moreover, the changes in plasma cholesterol levels occur very slowly with oral dietary manipulation alone, and the hypercholesterolemic patient is usually discouraged within a few months of adhering to the diet because of the slow apparent progress. Moreover, it is difficult to achieve reductions of plasma cholesterol levels of greater than 8–10% by dietary manipulation alone.

The advantages of using a totally intravenous diet to stimulate reduction of plasma cholesterol levels are several: (1) the components of the diet can be finitely defined and precisely administered directly into the blood stream where they can immediately become involved in the appropriate biochemical reactions; (2) the cholesterol reduction effect of the optimal mixture of amino acids occurs rapidly to effect 40–60% reductions, which are unprecedented with any other single form of anticholesterol therapy; (3) the patient not only achieves prompt gratification and reward for the investment biochemically but also symptomatically as hyperlipidemia is reduced with corresponding decreased blood viscosity and increased microvascular perfusion; and (4) regression of atherosclerosis can be documented indirectly and/or directly by techniques that are currently rather crude but are destined to improve in simplicity, sophistication, and resolution.

This technique allows the application of clinical biochemistry directly to the management of a complex metabolic disorder with gratifying early biochemical and clinical results. The technique also allows a degree of control of the myriad biochemical processes of the body that is currently impossible to achieve with oral or enteral regimens. Thus the importance of any or all of the individual active components in the solution can be established finitely *via* direct intravenous infusion and without potentially detrimental modification by the digestive and absorptive processes of the alimentary tract. Eventually, however, the principles derived from the conscientious, meticulous study of the reactions and responses of patients with atherosclerosis to the intravenous nutrient mixtures herein described should allow the development of oral and enteral dietary formulations that will mimic or duplicate the biochemical milieu of the currently infused substrates after digestion, absorption, and assimilation. It is important that our efforts be directed toward achievement of these goals to allow the patient who has benefited from an intravenously induced hypocholesterolemia to maintain the accrued advantages after returning to a judicious oral diet after the intravenous therapy. The ultimate goal will be to prove the biochemical importance of maintaining much lower plasma cholesterol levels than we have accepted and tolerated as normal in the past not only to arrest and reverse atherosclerosis, but ultimately to prevent atherosclerosis. It is anticipated that this relatively pure biochemical approach to the management and control of the number one pathophysiologic process adversely affecting the health and longevity of our population will be rewarded with highly significant reductions in morbidity and mortality and greatly increase understanding of basic and clinical lipid and lipoprotein chemistry.

Discussion

DR. EDWARD M. COPELAND, III (Gainesville, Florida): The work that Dr. Dudrick has presented represents a culmination of 7 years of effort. I was privileged to see this project begin when I was still in Houston and have had the chance to follow its progress by various visits to Dr. Dudrick's laboratory.

I have had access to the manuscript and you, the audience, have not. To be able to give the amount of data contained in this manuscript in 10 minutes is impossible. I implore you to read the manuscript when it becomes available. It is excellent and represents a Herculean effort for which Dr. Dudrick and his colleagues should be congratulated.

Many questions arose while reading the paper. The solution does not work if given by gut. Dr. Dudrick might comment as to why. Will it work in the "garden variety" atherosclerotic patient as opposed to someone who has hereditary hyperlipidemia? Obviously, there are more people with "garden variety" atherosclerosis than with the other types of hyperlipidemia diseases. Does it work possibly in those patients with atherosclerosis but no hypercholesterolemia?

The published formula, called "Atheromine," is a range of concentrations for the individual amino acids, rather than a specific concentration for each amino acid. The concentration range was derived from multipe formula changes in both rabbits and patients to get a solution that would lower cholesterol maximally.

A further question, therefore, is: those of us who will use the solution, will we have to measure the serum and urine amino acids, as well as plasma cholesterol and various other lipids, to manipulate the concentration of the substrates to produce the data that you have, or will there be a single solution that we will be able to use much like that which evolved for the treatment of renal failure and hepatic failure?

DR. HENRY BUCHWALD (Minneapolis, Minnesota): I thank Dr. Dudrick for the privilege of reviewing this manuscript beforehand. I start with a few historic remarks: the ability of intravenous hyperalimentation solutions to depress lipid levels was first noted by Dr. Judah Folkman in 1972 in his work with total parenteral nutrition (TPN) solutions for glycogen storage disease. This work was confirmed by Dr. Starzl, our Program Chairman, and associates in 1973, in the use of TPN solutions as a preoperative test of potential efficacy before consideration of a portacaval shunt in patients with familial homozygous hyperlipoproteinemia. Again, this effect of TPN solutions was confirmed by Torsuch and Lees (1975), Stein and Meiny, and associates (1975), Cywes et al. (1976), and Yamashita and co-workers (1986). Most important, all of these studies showed that once you stopped infusion of TPN solutions, the hypolipidemic effect disappeared and the lipid levels returned to baseline.

I next turn to some of the items in Dr. Dudrick's paper and comment on them. I am a little confused about the atherosclerosis in the rabbits used in these experiments. Traditionally, if you give rabbits enough oral cholesterol, or enough of a dietary stimulus, to raise their cholesterol concentration over 1000 mg/dL, and then continue to follow these rabbits, they get progressive atherosclerotic disease, and it is ever progressive disease until they die. Thus, I question the validity of the visual inspection used by Dr. Dudrick of these lesions. Could his means of assessment not have been refined by use of scanning electronic microscopy, Folch analysis of vessel lipid content, or even simple dye staining to obtain a more accurate assessment of progression and regression? Finally, with respect to the animal data, I do not understand how he gets his numbers of 85% and 95%.

In terms of the clinical data, I was privileged to read in Dr. Dudrick's manuscript about four case studies. Dr. Dudrick, you had preoperative and postoperative arteriograms in all four patients, but in only one patient, the one you cited in your presentation, did you conclude that there was actual evidence of atherosclerotic regression on the arteriogram. Your data showed increases in flow rate, changes in symptoms, and alterations in Dopplers, but only one case showed, as I read the manuscript, a decrease in atherosclerosis.

The TPN solution advocated by Dr. Dudrick has three features that distinguishes it from the standard TPN solutions. There is a decrease in glycogen, a decrease in alanine, and an increase in arginine. Most interestingly, if the same solution is given orally, as has been noted by Dr. Copeland, the effect is negated. I cannot understand why.

I conclude from the data presented that this is an interesting pilot study. The work needs to be repeated in a randomized controlled trial in humans and it should not precede a commercialization at this point of a product.

I ask Dr. Dudrick several questions: what is the significance of these changes in these three basic amino acids? Why are glycine, alanine, and arginine altered so differently from their concentrations in other TPN solutions? With Dr. Copeland, I would like to ask, must this formula be individualized per patient or can a standard formula be developed, or can the blending of the formula be codified so that other investigators can do the same thing?

Again, I repeat the question why doesn't your solution work orally? Amino acids are absorbed without change from the intestinal tract; thus, why would this solution not work when administered orally?

Finally, what do you postulate is the biochemical mechanism by which your solution, in an isocaloric state, works to lower the serum lipids?

DR. HAROLD URSCHEL, JR. (Dallas, Texas): That was a fascinating presentation, and it could potentially mobilize the large cardiovascular labor force from bench work to more creative pursuits.

Previous search for the ideal "Draino" included our experiments with intra-arterial hydrogen peroxide in the late 1960s and early 1970s. It was based on the fact that hyperbaric oxygen reduced blood lipids and in some cases reversed atherosclerosis.

We must be careful in extrapolating the efficacy of any antiatherosclerotic drugs solely on the base of animal atherosclerosis, particularly hyperlipidemic rabbit atherosclerosis. With intra-arterial hydrogen peroxide, these lesions could be reversed in virtually 100% of animals completely. Even the induced hyperlipidemic lesions in primates consistently disappeared with intra-arterial hydrogen peroxide.

We tried this in over 100 patients with significant atherosclerotic obstructive lesions, and the results varied dramatically from total reversal to minimal regression or no effect.

A 95% stenosis in a unilateral vertebral artery not amenable to surgery in a patient with severe basilar artery insufficiency disappeared with 19 treatments of intra-arterial peroxide. The patient became asymptomatic for 4 years and died of carcinoma.

These data were presented to the Society of Vascular Surgery in 1975. It was totally ineffective in occluded arteries and in severely calcified arteries. These are similar limitations to angioplasty (PTCA) today.

I ask Dr. Dudrick what are the limitations of his technique. One of the arteries that we saw treated was totally obstructed (the right coronary artery). The rapidity that Dr. Dudrick showed the angiograms reminded me of Ken Cooper's speed of showing them when he was trying to demonstrate the effect of exercise on reversal of atherosclerosis. When you flash those angiograms past that quickly, it is difficult to assess the results.

We used hydrogen peroxide for cardiac resuscitation and treatment of acute myocardial infarction by retroperfusion of the coronary sinus, but discontinued its use because of the effective dose response was so close to the toxic effect on the enzyme system. I would like to know about the toxic effects in your dose-response curves and any deleterious side effects.

I think this is exciting, but caution should be employed until the clinical results are carefully assessed.

DR. ANTHONY M. IMPARATO (New York, New York): Dr. Dudrick is to be complimented on the exhaustive laboratory investigations that he has done with rabbits and the follow-up attempts to duplicate the results in humans. Carotid bifurcation plaques as seen in the operating room in both symptomatic and asymptomatic ischemic stroke patients vary considerably from patient to patient sharing in common mainly their localization at the carotid bulb and their content of fibrous tissue. They may be and probably are the prototype arterial lesions that cause ischemia in other parts of the body as well. Their evolution can be deduced, probably accurately, from observations in humans in the operating room and subsequent microscopic study.

May I lay the groundwork for two questions that I would like to ask by showing some slides?

(Slide) A carotid plaque appears to start as fibro-intimal thickening (Slide) which can be reproduced in the experimental animal by specific alterations of blood flow without alteration of diet. These are some of the models and these are the lesions at 1 year.

In humans it can progress to fibro-intimal plaque with intraplaque hemorrhage totally contained within the fibrous covering. (Slide) That is an early hemorrhage contained. (Slide) Gradual transformation of the hemorrhage to atheromatous debris can occur (Slide) until the so-called cholesterol abscess results. At any stage in the evolution of this plaque, thrombosis of the vessel can occur or embolization of a portion of the arterial wall producing ischemic stroke.

(Slide) This shows the portion of the arterial wall that is missing having embolized.

Would Dr. Dudrick speculate as to how lowering serum cholesterol in the human might influence this complex process of plaques' evolution? By what mechanism might ischemia be improved or relieved by lowering cholesterol?

DR. HIRAM C. POLK, JR. (Louisville, Kentucky): Dr. Dudrick, in response to specific inquiry from Council, you said that you would present objective evidence in humans of regression of atherosclerosis as well as describe the nature of the solution used. Would you specifically respond on both those counts, taking an extra minute to do so in your closing discussion?

DR. JOHN H. SIEGEL (Baltimore, Maryland): I congratulate Dr. Dudrick on opening up a whole new era on nutritional therapy, but I have some questions. It seems that a good deal of the response he has shown is due to a hypocaloric-controlled starvation in which he specifically reduced gluconeogenic amino acids and, therefore, to some extent also reduced lipogenic precursors.

I wonder if he could address the following questions. In both the experimental model and in humans, was the total caloric input in excess of metabolic needs, or was the caloric input negative with respect to the actual metabolic rate that these animals had?

Secondly, what effects did this nutritional program have on insulin secretion relative to the hypercaloric atherosclerotic diet where insulin is increased, since elevated insulin output in the control hypercaloric phase might cause increased synthesis of fatty acids? Was there a specific negative insulin secretory effect of the TPN solution used during the hypocaloric therapeutic period? Did those levels change?

Thirdly, is there any evidence of alteration in free fatty acid re-esterification before or after the therapeutic TPN period, since we did notice that when he restarted lipids he raised triglyceride levels severely. Does the TPN antiatheroslerosis diet therapy alter the tendency for re-esterification of administered lipids?

DR. GEORGE H. A. CLOWES, JR. (Boston, Massachusetts): Dr. Dudrick, before you come up, I would like to ask one question also. It seems to me that what you have shown us is that substitution of certain amino acids, perhaps for caloric value or for synthetic value, have had what looks like a beneficial effect.

I ask whether you have any data as to actually how these amino acids are used, studies with a radioactive tracer, or some other system?

DR. STANLEY J. DUDRICK (Closing discussion): My sincere thanks to all of the discussants. I greatly appreciate the comments and questions; each one is valid and appropriate.

This vital area is one of complex biochemistry. I do not believe that we can describe, explain, manage, or treat every manifestation or complication of atherosclerosis in the same way. As Dr. Imparato showed, there are various stages in the development of complex atherosclerotic lesions. There are also various causes, contributing factors, initiating factors, classifications, distributions, complications, etc. One must do the best one can in preventing and treating the usual presenting problems, and what cannot be managed adequately biochemically will require operative management.

Dr. Clowes, there is an enormous amount of work in the basic science literature showing positive correlations between the dietary intake of various sources of food and mortality rates secondary to coronary heart disease. In men between the ages of 55 and 59, animal protein had the highest positive correlation of 0.78 with a p value of less than 0.05, followed by cholesterol (0.76), meat (0.70), total fat (0.68), eggs (0.67), sugar (0.64), total calories (0.63), and animal fat (0.63). No correlation is demonstrable at $p < 0.05$ for plant sterols, fish, vegetable fat, or vegetables, and a negative or beneficial correlation exists for starch or complex carbohydrate (−0.46) and vegetable protein (−0.40).

The formulation of this solution resulted from a series of tedious, obsessive-compulsive laboratory experiments and observations. The solutions that were most effective in the rabbits and most effective in humans resembled plant or vegetable protein in their amino acid composition. Having started with intravenous amino acid mixtures with profiles derived from animal protein, which includes all kinds of meat, cheese, eggs, milk, even skim milk, we arrived at a mixture of amino acids that is similar to that of plant protein. Therefore, it appears that we have documented the wisdom of ingesting a vegetarian diet, which has been well described in the basic literature, and we have done it under the precise, well-controlled nutritional and metabolic conditions that can only be achieved intravenously.

Dr. Clowes, we have demonstrated reproducible correlations between plasma amino acids and plasma cholesterol concentrations in a series of meticulous studies in several atherosclerosis patients. Of the 18 component amino acids in the intravenous mixture, very strong inverse correlation between the plasma amino acid and the plasma cholesterol level was demonstrated for arginine, phenylalanine, isoleucine, valine, serine, aspartic acid, and leucine in decreasing order of importance and significance. The inverse correlations are not as significant for alanine, glycine, proline, or tryptophan. No correlation could be demonstrated between plasma cholesterol and plasma lysine levels, and there have been several published reports indicating that high arginine to lysine ratio has a positive correlation with lowering plasma cholesterol in animals.

Plasma methionine, tyrosine, and threonine show little or no correlation with plasma cholesterol levels, whereas histidine, glutamic acid, and cysteine show direct correlations between their plasma levels and plasma cholesterol level in increasing order of significance. Metabolite amino acids that are not in the mixture but appear in the plasma in significant amounts include citrulline, ornithine, glutamine, taurine, hydroxyproline, and asparagine. Strong inverse relationships exist for citrulline and ornithine, which are derivatives of arginine, the most important amino acid in the mixture. The inverse relationship for glutamine and cholesterol is less impressive, and the relationships between taurine, hydroxyproline, and asparagine are direct in increasing order of significance.

Dr. Buchwald, evidence for regression of atherosclerosis has been demonstrated clearly in three patients reported in this paper. There was not sufficient time in this 10-minute presentation to show all of the data included in the 25 figures in the paper.

Dr. Polk, the formula is presented with upper and lower limits for each component amino acid and compared with the currently available clinical intravenous amino acid mixtures. Starting at the median value for each amino acid, the mixture is individually formulated optimally for each patient based on plasma and urine amino acid and cholesterol levels. To date, this is the only manner in which the formula can be used clinically, but we are currently working toward an FDA approved formula suitable for mass production and distribution. The components of the mixture and the principles for their safe and effective formulation and use in patients are outlined in the paper. Your second question has been answered in my response to Dr. Buchwalds' query.

Dr. Copeland, when the amino acid mixture is administered *via* the alimentary tract in either rabbits or patients, the digestive processes destroy the effectiveness of the active ingredients in reducing plasma cholesterol or inducing regression of atherosclerosis. Therefore, we are currently engaged in studies to produce amino acid mixtures that when digested and absorbed, will mimic the milieu that we induce by direct central venous infusion.

I regret that there is insufficient time to discuss or answer the other comments and questions.

The Control of Diabetes Mellitus (NIDDM) in the Morbidly Obese with the Greenville Gastric Bypass

WALTER J. PORIES, M.D.,* JOSE F. CARO, M.D.,† EDWARD G. FLICKINGER, M.D.,*
H. DIANE MEELHEIM, F.N.P.,* and MELVIN S. SWANSON, PH.D.*

Since February 1, 1980, the identical standardized Greenville Gastric Bypass has been performed in 397 morbidly obese patients with an operative mortality rate of 0.8%. The operation effectively controlled weight and maintained satisfactory weight loss even after 6 years (mean weights and ranges: Preoperative: 290 lbs (196–535); 18 months: 175 lbs (110–300); 72 months: 205 lbs (140–320). The gastric bypass favorably affected non-insulin-dependent diabetes (NIDDM), hypertension, physical and role functioning, and several measures of mental health. Rigorous follow-up (97.5% over 6 years) revealed that health problems were common in postoperative patients; there were nine late deaths. Abnormal glucose metabolism was present in 141 (36%) of 397 patients before surgery: NIDDM was present in 88 patients (22%) and 53 patients (14%) were glucose impaired. Of these, all but two became euglycemic within 4 months after surgery without any diabetic medication or special diets. The most recent 42 morbidly obese patients with NIDDM were studied intensively. In that cohort, fasting blood glucose, fasting insulin, and glycosylated hemoglobin returned to normal after surgery; insulin release, insulin resistance, and utilization of glucose improved sharply. The normalization of glucose metabolism after gastric bypass may not be related solely to weight loss and restriction of caloric intake, but may also be due to the bypass of the antrum and duodenum.

DIABETES MELLITUS is a frequent complication of morbid obesity. At least 25% of the morbidly obese have non-insulin-dependent diabetes mellitus (NIDDM) and an additional 10% demonstrate impaired glucose metabolism. This unusually high prevalence of diabetes may account for the high mortality of the morbidly obese from heart disease, atherosclerosis, and stroke.

From the Department of Surgery and the Division of Endocrinology, Department of Medicine, East Carolina University School of Medicine, Greenville, North Carolina

We have operated on 397 morbidly obese patients since February 1, 1980, and of these patients, 88 (22%) were afflicted with diabetes mellitus, whereas 53 (13%) demonstrated impaired glucose metabolism. A standardized gastric bypass operation was performed on all patients. Although we anticipated the diabetes mellitus of these morbidly obese patients would improve with their surgically induced weight loss, we were surprised by the rapidity of the improvement of glucose metabolism and the return to euglycemia even though the patients were still clearly morbidly obese and were still within 10–20 lbs of their preoperative weights. This report details our observations of the effect of the gastric bypass on diabetes mellitus. We also describe the effectiveness of the operation in controlling morbid obesity, reversing hypertension, and restoring functional effectiveness.

Methodology

From February 1, 1980 to February 1, 1987, we performed the identical standardized Greenville Gastric Bypass in 397 morbidly obese patients. The group included 343 women (86.4%) and 54 men (13.6%) of which 326 (82.1%) were white and 71 (17.9%) were black. The mean age was 37.6 years (range: 16–65).

Each patient was evaluated with a thorough medical assessment, an interview with a psychiatrist, and several instruments to measure mental health, physical and role functioning, economic status, and educational levels. Additional evaluations, including treadmill tests, cardiac catheterizations, endoscopies, and radiocontrast studies were done in some patients when indicated by the initial evaluation.

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

Supported in part by a grant from the Robert Wood Johnson Foundation and NIH PO1-DK36296.

Submitted for publication: April 23, 1987.

Every morbidly obese patient without known diabetes mellitus had a 75-g oral glucose tolerance test (OGTT), as recommended by the National Diabetes Data Group[1] to determine whether they were truly nondiabetics. The 42 morbidly obese patients with diabetes who were recently operated on also had a 25-g intravenous glucose tolerance test to determine the rate of glucose disappearance (kg rate) and insulin concentrations before surgery. Of these 42 patients, 32 had the same tests 1 year after the gastric bypass surgery. Plasma glucose was measured by the Beckman-developed oxygen rate method.[2] Insulin was measured with the double-antibody method.[3] In addition, glycosylated hemoglobin was measured in these patients before and 1 year after surgery by affinity chromatography.[4,5]

All patients, whether referred by other providers or self-referred, were considered for initial evaluation. A patient was considered eligible for the surgery if: (1) he or she exceeded ideal body weight (as defined by the 1983 median weight of the Metropolitan Life Insurance Tables) by at least 100 lbs or if of short stature by 100%, (2) if the patient was an acceptable surgical risk, (3) if the patient was considered capable of understanding the operation and the postoperative consequences, and (4) if the patient gave informed consent.

Patients were usually admitted to the hospital on the day before surgery except for those in cardiorespiratory failure or those with other significant medical problems. Patients with such complications were often admitted several days before surgery to improve their surgical risk. Recently we have admitted a limited number of low-risk patients on the day of surgery, and these individuals have done well.

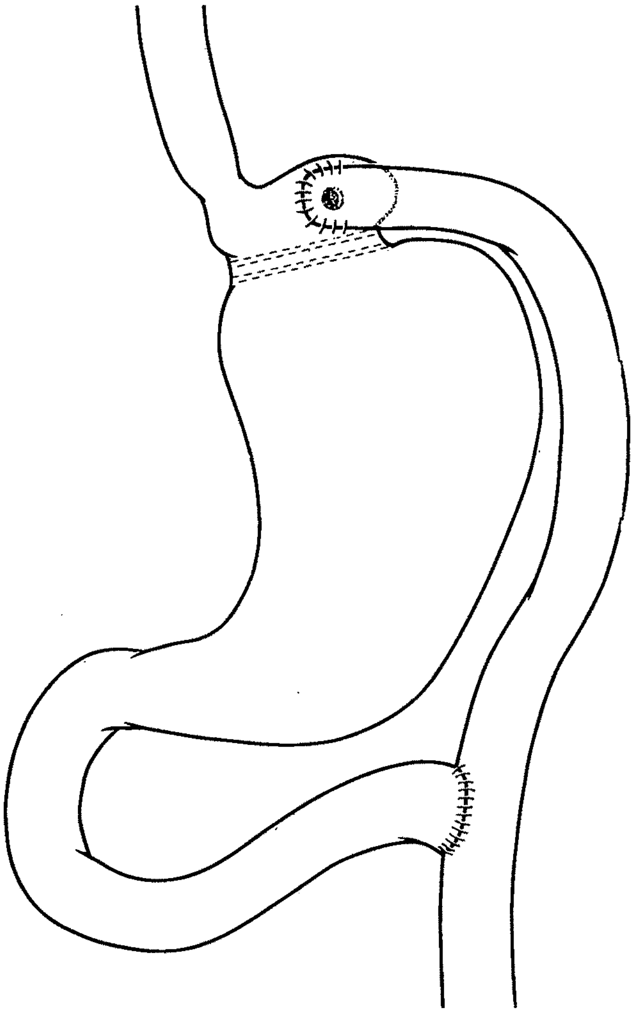

FIG. 1. The Greenville modification of the gastric bypass consists of 30-mL proximal gastric pouch joined to a 40-cm Roux-en-Y jejunal loop with a 0.8-mm gastroenterostomy.

The Greenville Gastric Bypass, a modification of the procedure devised by Mason,[6] has previously been described[7] in detail; a diagram of the procedure is shown in Figure 1. A Gomez retractor is useful. The abdomen is entered through a midline incision. If the exploration does not demonstrate contraindications to the procedure, specimens of blood, fat, liver, and muscle are taken for our basic science studies. Dissection around the upper portion of the stomach is begun by inserting the index finger gently into the angle at the cardia to the left of the esophagus. At this point there is a weak, thin area of the posterior peritoneum that is easily entered by the dissecting finger. The dissection is gently continued behind the esophagus and cardia and the finger brought out, not at the right side of the esophagus but between the ascending branches of the left gastric artery 2.5–3.0 cm below the esophagogastric junction. A large Malecot catheter (Division of Bard, Inc., Bard Urological Division, Murray Hill, NJ), from which the bulbous end has been cut, is used to pull a double-headed TA 90 Auto Suture stapling instrument (US Surgical Corp., Norwalk, CT) through the passage. A proximal pouch measuring 4 cm in width and 1.5 cm in height is then prepared by firing the staples. A figure-of-eight suture is placed at each end of the staple line to close the ends securely and to serve as guy sutures. The jejunum is divided at its apex, about 30–40 cm from the ligament of Treitz with the GIA stapling instrument and the distal end is then sutured to the gastric pouch. The anastomosis is sewn to fit snugly around a 0.8-cm Salem Sump tube (Sherwood Medical, St. Louis, MO) in two layers with continuous Prolene. The Roux-en-Y enteroenterostomy is then completed by joining the proximal jejunum end-to-side to the distal jejunum with GIA and TA 55 (US Surgical Corp.) stapling instrument. It is important to fasten the Roux loop to the mesocolon to prevent an internal hernia and to oversew any bleeders in the enteroenterostomy before closing it. The abdomen is closed with a running double-stranded 0 PDS absorbable suture. The skin is stapled. The operation can usually be performed in 60–75 minutes; blood loss rarely exceeds 300 mL.

TABLE 1. *Weight Loss after Gastric Bypass for the RY22 Cohort*

Time	N*	Mean Weight (lbs)	Mean % of Original Weight	Mean % of Ideal Body Weight
Before operation	397	290 (186–535)		212 (140–377)
1 month	251	261 (180–480)	90 (80–100)	191 (131–332)
6 months	323	207 (100–418)	72 (42–93)	152 (73–282)
12 months	240	184 (107–397)	63 (32–88)	134 (85–268)
18 months	172	175 (110–300)	61 (40–88)	120 (88–205)
24 months	160	176 (105–367)	61 (37–84)	130 (90–248)
36 months	120	187 (119–359)	64 (43–91)	138 (91–243)
48 months	99	188 (114–360)	65 (41–95)	139 (87–243)

Effect of the Gastric Bypass on RAND Mental Health Measures and Physical and Role Functioning

The effects of morbid obesity and the gastric bypass on mental health, physical and role functioning, *i.e.*, functional effectiveness were measured with the RAND instrument, the Obesity Awareness Scale (OAS), Eating Restraint Questionnaire (ERQ), Multidimensional Health Locus of Control (MHLC), the Zung Self-rated Depression Scale or SDS, and the Family Inventory of Resources for management (FIRM) before operation and during the course of follow-up in the most recent 120 patients.

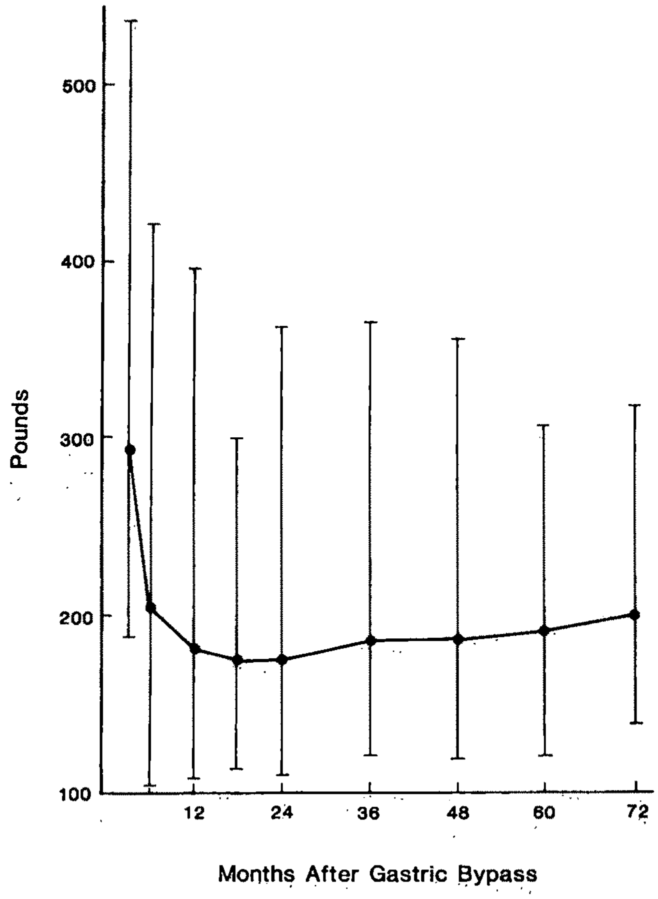

FIG. 2. Weight loss in pounds after gastric bypass in 397 morbidly obese patients.

Results

Follow-up

Follow-up has been rigorous. Of the 397 patients, only 10 did not keep long-term clinic appointments. Fortunately we have maintained contact with eight families of these 10 patients (97.5% follow-up).

Control of Weight

Weight reduction in these patients has been dramatic and well maintained over the 72 months of follow-up. Table 1 and Figure 2 present the weight loss of all 397 patients who have had the gastric bypass during the time intervals after surgery, in terms of mean weight in pounds, mean percentage of original weight, and mean percentage of ideal body weight. (Ideal body weight is determined from the midpoint of the "medium" standard of the Metropolitan Life Insurance Tables of 1983.)

If morbid obesity is defined as 100 lbs over ideal weight, 94% of the patients are "cured" within 2 years. There is, however, some weight gain between 24 and 72 months (176–205 lbs; 14%), reflecting a minority of individuals who learned to "outeat" their pouch and their dumping response by almost continuous snacking. These patients, *i.e.*, those who began to regain their weight, were the only ones given dietary limitations. Although we have had a few dietary failures, most patients will respond to the "Ensure Diet" (Ross Laboratories, Columbus, OH) (taking two cans of this supplement as the only caloric intake two or three times a week) or to formal dietary instruction by a trained dietician.

TABLE 2. *Effect of the Gastric Bypass on Diabetes*

	Before Operation	After Operation
Glucose Impaired	53	—
Diabetes Mellitus (NIDDM)	88	2
Receiving insulin	20	2
Receiving oral agents	13	1*

* One patient receives both insulin and an oral agent from her physician.

The Reversal of Diabetes Mellitus by the Gastric Bypass

The effect of the gastric bypass on adult onset diabetes mellitus (NIDDM) is the most significant finding of this study (Tables 2 and 3). Diabetes Mellitus (NIDDM) was present in 88 (22%) and impaired glucose tolerance was present in 53 (13%) of the 397 patients according to the criteria of the American Diabetes Association. All but two patients (99%) became and have remained euglycemic since surgery.

This normalization of glucose metabolism occurs with surprising speed. Frequently, patients became euglycemic within 10 days, even if they required over 100 units of insulin before surgery. The effect does not appear to be related solely to weight loss or decreased caloric intake, but may also be due to the bypass of the neuroendocrine axis of the antrum and duodenum.

The most recent 42 patients with diabetes were studied intensively. Of these, 12 had been receiving insulin, nine were receiving sulfonylureas, and another two were receiving both medications before the gastric bypass. Of these 42 patients, none now receive insulin and only one requires sulfonylureas. In all, fasting blood glucose, fasting insulin, and glycosylated hemoglobin were restored to normal levels. Insulin release, insulin resistance, and utilization of glucose were sharply improved. Although the maximum insulin release *per se* is not significantly different, these data should be considered in view of the preoperative and postoperative fasting insulin levels, *i.e.,* the basal values of 53 and 14 μU/mL. Thus the preoperative insulin release above basal was 23 μU/mL, whereas the postoperative response of the pancreas to the glucose load was 48 μU/mL, a significant improvement.

TABLE 3. *Effect of the Gastric Bypass on Measures of Glucose Metabolism*

	Before Operation (N = 42)	Year After Operation (N = 32)
Fasting blood glucose (mg%)	213 ± 15	117 ± 8
Fasting insulin (μU/mL)	53 ± 7	14 ± 1
Glycosylated hemoglobin (%)	12.3 ± 1.1	6.6 ± 0.6
Maximum insulin release (μU/mL)	76 ± 11	62 ± 15
Kg rate (%/min glucose disappearance)	0.65 ± 0.08	0.88 ± 0.07

TABLE 4. *Effect of the Gastric Bypass on Hypertension (N = 397)*

	Before Operation		After Operation	
	N	%	N	%
No. of hypertensive patients	225	56.7	73	18.4
Total no. receiving medication	144	36.3	53	13.3
Beta blocker	33	8.3	11	2.8
Diuretic	98	24.7	34	8.6
Vasodilator	11	2.8	6	1.5
Calcium blocker	2	0.5	2	0.5

The Control of Hypertension

Table 4 shows that of the 225 patients who were hypertensive (>140/90 mmHg) before surgery, only 73 remained so after the gastric bypass, a 68% decrease in the number of hypertensive patients. Similarly, the number of hypertensive patients requiring medication decreased from 144 to 53, a drop of 63%.

Effect of the Gastric Bypass on RAND Mental Health Measures and Physical and Role Functioning

The effects of morbid obesity and the gastric bypass on functional effectiveness were measured in our last 120 patients with the instruments listed under Methodology. These data will be reported separately, but in essence demonstrate that the operation sharply improves physical and role functioning, but that the mental health improvements noted during the first year may not be maintained.

Perioperative and Late Complications

The perioperative and late complications associated with this series of gastric bypass operations are summarized in Table 5.

TABLE 5. *Complications Associated With Gastric Bypass (N = 397)**

	N	%
Deaths		
Perioperative (2 Sepsis, 1 MI)	3	0.8
Late		
2 sepsis		
1 cancer of the larynx		
2 automobile accidents		
3 suicides

Summary		
Patients with complications	226	58.9
Deaths related to surgery	3	0.8
Reoperated	8	2.1
Readmitted	29	7.6

* As of February 1, 1987.

The perioperative mortality rate of 0.8% is low (3/397) for this group of high-risk patients with such complicating preoperative factors as Pickwickian syndrome, inadequately managed diabetes, cardiopulmonary failure, asthma, and disabling arthritis. The 30-day mortality rate (the usual way of defining perioperative mortality) is 0.5%, but since the third patient died on the 35th day of complications resulting from her operation, we have included her as a perioperative death in the summary Table 5. All of the perioperative complications occurring within the first 30 days after surgery are listed in Table 6.

Of the 397 patients who had surgery, 11% had a complication serious enough to prolong their hospital stay; 31.2% required readmission during the 6 years of follow-up for a problem directly or indirectly related to the obesity or the gastric bypass.

Patients who have gastric bypass operations require considerable postoperative medical support. During our 72 months of rigorous follow-up, 98% returned with a large variety of health problems; these are listed in Table 7. Although a number of these concerns were not directly related to the gastric bypass, many were. Problems such as depression, vitamin deficiencies, and dumping may be minor in terms of surgical statistics but are certainly major concerns for the patient and for those who bear the costs for the readmissions and extra office visits. Further, these complications may not become apparent for years, underscoring the great need for long-term follow-up of this and of other operations for morbid obesity.

* As of February 1, 1987.

Most disturbing are the nine late deaths, a late mortality rate of 2.3% (9/397). Although no deaths seem to be directly related to the surgery, they raise concerns. The two deaths from automobile accidents, the three suicides, and the one death from cirrhosis suggest that the gastric bypass does not alleviate the depression commonly seen in the morbidly obese; in fact, the dramatic change in body image and forced modification of eating behavior may exacerbate it in a few patients. Similarly, the two deaths from sepsis and the death from cancer of the larynx raise questions about the effect of the induced malnutrition on immunocompetence in these patients. A tenth late death is expected soon: a woman dying of AIDS, probably acquired from a blood transfusion given during a plastic surgical procedure over a year after her gastric bypass. This mortality will raise the late death rate to 2.5% Unfortunately, we do not have reliable comparison figures for the illness or mortality rate of morbidly obese individuals who did not have surgery.

Discussion

NIDDM or Type II diabetes mellitus represents approximately 85% of all patients with diabetes. It is a heterogeneous disorder characterized by defects in insulin action and insulin secretion.[8–12]

When NIDDM is associated with obesity, insulin resistance significantly worsens. Over 75% of patients with NIDDM are obese and those who are morbidly obese (defined as at least 100 lbs or more than 100% over their ideal body weight) are most frequently refractory to insulin or sulfonylurea therapy, dietary counseling, or physical therapy.

Weight reduction clearly improves NIDDM and dietary control remains the hallmark of treatment for this disease. Consequently, dieting has always been a mainstay in the clinical management of NIDDM. Although the amelioration of NIDDM after jejunoileal bypass had been recognized for a long time, Ackerman[13] was apparently the first to note the rapidity (in days) with which objective improvements in carbohydrate metabolism occurred. Previously the improvement associated with intestinal bypass was considered to be a direct result of massive weight loss, but Ackerman speculated that the early return to glucose tolerance, even during the period of perioperative stress, must have a more complex explanation. He considered such possibilities as decreased carbohydrate ingestion, glucose malabsorption, and the diminution in measured gastric inhibitory polypeptide (GIP) and its insulinotropic effect after intestinal bypass. Halverson et al.[14] have reported similar findings after gastric bypass. They described alterations in glucose tolerance, insulin response, and insulin sensitivity 20 months after surgery. Excess weight loss was accompanied by improvements in insulin receptor number, basal hyperinsulinemia, and glucose tolerance. They also described an unexpected rise in GIP and insulin after the ingestion of oral rather than intravenous glucose in patients after operation, perhaps accounting for the episodic hypoglycemia sometimes seen in these individuals after gastric bypass. Herbst et al.[15] confirmed similar findings in morbidly obese diabetics who had gastric restriction operations and credited the improvement to increased insulin receptors. Schrumpf et al.[16] also reported the positive effect of the gastric bypass on glucose tolerance in obesity and credited this change to lowered basal insulin secretion and increased hepatic extraction of insulin.

Our population of morbidly obese patients with NIDDM has the same characteristics as other similar populations previously described.[14,15,17–19] These patients have fasting hyperinsulinemia, fasting hyperglycemia, and a decreased glucose disappearance rate currently attributed to overall insulin resistance, increased glucose production by the liver, and reduced peripheral glucose utilization. The increment of insulin secretion by the pancreas during the first 10 minutes after the administration of 25 g of glucose intravenously is severely decreased, characteristic of the abnormal first phase of insulin release seen in patients with NIDDM. Furthermore, the glycosylated hemoglobin is increased, indicative of long-term hyperglycemia.

The mechanism of insulin resistance in these severely obese patients with NIDDM currently is unknown. We have developed methodologies to study the three major target organs of insulin action in humans: the liver, muscle, and adipose tissue.[20–23] We have found that the insulin receptor kinase is greatly decreased, compared with controls, in liver and adipose tissue, but not in skeletal muscle. Since the insulin receptor kinase might be involved in the intracellular message of insulin action, our studies so far have provided the first demonstration of a functional abnormality of the insulin receptor in NIDDM. In the muscle, the defect in insulin action might be distal to the insulin receptor kinase.

After gastric bypass surgery there is a dramatic improvement in overall carbohydrate metabolism, insulin action, and insulin secretion in the absence of pharmacologic therapy. From the clinical point of view, the most important observation is that the patients can maintain normal glycosylated hemoglobin. However, it should be recognized that if they are challenged with 25 g of glucose intravenously, it is clear that the ability of the pancreas to secrete insulin and the peripheral tissues to utilize glucose, although greatly improved, is not normal. However, under physiologic conditions, rarely, if ever, do these patients encounter a 25-g glucose load in blood within 1 minute.

The mechanism of improvement of NIDDM after gastric bypass is, no doubt, complex and due to a num-

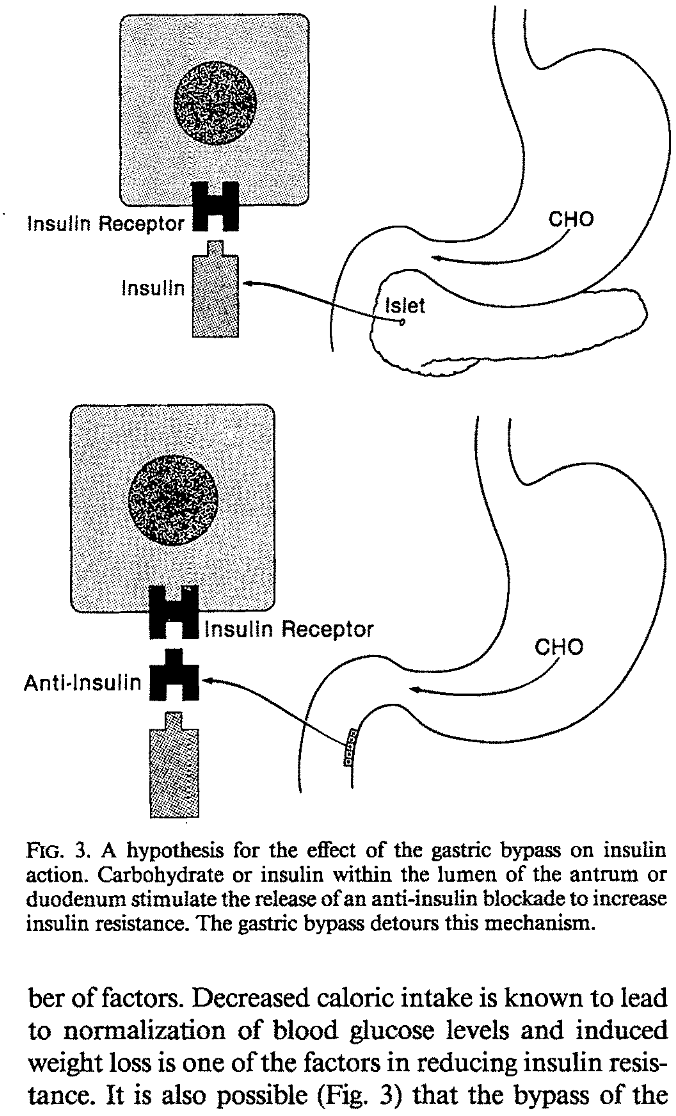

FIG. 3. A hypothesis for the effect of the gastric bypass on insulin action. Carbohydrate or insulin within the lumen of the antrum or duodenum stimulate the release of an anti-insulin blockade to increase insulin resistance. The gastric bypass detours this mechanism.

ber of factors. Decreased caloric intake is known to lead to normalization of blood glucose levels and induced weight loss is one of the factors in reducing insulin resistance. It is also possible (Fig. 3) that the bypass of the antrum and duodenum decreases the stimulation of endocrine cells to produce an anti-insulin blocking agent that influences the action of GIP. Most biologic systems have "stop and go" controlling systems; it is reasonable to expect that there is also an anti-insulin mechanism that responds either to high levels of glucose or insulin within the upper gut. We plan to explore this thesis with a prospective randomized comparison between the effect of the gastric bypass (which bypasses the antrum and duodenum) and the vertical banded gastroplasty (which does not) in a series of morbidly obese patients with NIDDM.

In summary, our series demonstrates that the Greenville version of the gastric bypass is an effective therapy for morbid obesity. The operation produces predictable control of weight, controls NIDDM in almost all patients, ameliorates most cases of hypertension, and sharply improves the functional effectiveness and quality of life in the morbidly obese. The operation is generally well tolerated and can be performed with a low mortality, but the patients must be followed closely for years because malnutrition, late complications of surgery, and psychiatric problems are not uncommon.

Acknowledgments

We gratefully acknowledge the help of P. G. Khazanie and Elizabeth Grigonis-Dean in the performance of the analyses and the collection of data and E. Finch in the preparation of this manuscript.

Discussion

DR. EDWARD E. MASON (Iowa City, Iowa): Thank you, Dr. Pories for calling attention to this effect general surgeons have on the ratio of benefit to risk in treating extreme obesity with stomach reduction surgery.

The effect is not peculiar to gastric bypass. (Slide) Vertical banded gastroplasty produces the same severe reduction in insulin requirement with the cost savings as much as $4000 in 5 years by elimination of the need for 100 units of insulin per day.

(Slide) What is happening? Vertical banded gastroplasty does not rearrange the gastrointestinal tract, which means that there is no deleterious effect on the absorption of iron, calcium, and certain vitamins, and probably no change in the release of digestive tract hormones.

(Slide) The benefit of all gastric reduction operations is dependent on careful measurement of pouch volume and the outlet, and over the long term of doing something to reinforce the outlet (Slide) to make sure it will not dilate.

(Slide) Vertical banded gastroplasty causes the same severe reduction in weight and usually the elimination of need for insulin, and in this and other ways is as effective as less physiologic operations that rearrange the digestive tract.

(Slide) Why does the insulin requirement drop from 100 to zero so rapidly? Before the patient is released from the hospital, the preoperative insulin level decreases from as high as 100 or 120, often to zero. This occurs probably because of the very severe reduction in glucose intake.

We know, however, according to Dr. Pories' presentation, that there was a doubling in the rate of glucose utilization. When does this occur? Does it occur in the first few days when the requirement for insulin drops? And, in those occasional patients who disrupt the operation or learn to overeat the restriction and regain weight, how long does it take for the cells to lose their insulin receptors?

We have an opportunity here to learn more about the mechanisms of the benefits we produce, and I look forward to hearing more about the mechanisms involved.

DR. EDWARD R. WOODWARD (Gainesville, Florida): We also have observed excellent weight loss after Roux-en-Y gastric bypass and early reversal of diabetes mellitus in nearly all cases. We have operated on 412 patients since 1982 using this procedure. A 2-year follow-up of 238 patients has revealed an average loss of excess weight of 66%. Three-year follow-up of 150 patients has revealed an average loss of excess weight of 64%. We have been particularly pleased with the 4-year follow-up in 67 patients where the average loss of excess weight has been 76%.

We have observed a higher incidence of marginal ulceration than that noted in this report. This diagnosis has been established in 30 of our patients, an incidence of 7%. Eighteen of these were refractory to medical therapy and required reoperation. It is interesting that in 17 of the 30 patients, a defect in the staple line had developed and most of the medically intractable patients were in this group. It appears the staple line defect permitted reflux of acid gastric juice from the main stomach.

In the last 2 years we have had considerable experience using a vertically stapled gastric partition with a Silastic® band controlling the pouch outlet. This is the method described by Dr. Henry Laws of Birmingham (Am J Surg 1981; 141:393–394.). We have noted the same early reversal of diabetes mellitus in these patients, indicating the likelihood that drastically reduced calorie intake is a major factor.

DR. BERNARD M. JAFFE (Brooklyn, New York): I, too, was privileged to review the manuscript. Dr. Pories asked if I would spend a moment speculating as to the possible mechanisms that resulted in improvement of insulin function.

One of the possibilities must be related to dietary changes. However, the documentation that glucose tolerance tests and euglycemic and hyperglycemic clamps resolve so rapidly after operation suggests that it is simply not a matter of dietary glucose or dietary carbohydrate.

Another possible mechanism includes an abnormality in gastrointestinal hormones, and in response to Dr. Pories' request, I have thought about some possible humoral mechanisms that could be involved.

Pancreatic polypeptide is known to be involved in the control of insulin release, and levels of PP are profoundly suppressed in obesity. On the other hand, despite these two pertinent observations, PP is unlikely to be the mediator of this phenomenon. Reversal of the abnormality in PP requires restoration of normal weight, *i.e.*, a much slower effect than that observed in these clinical experiments. Therefore, PP is not the agent.

Somatostatin is another possibility, and obviously bypassing of the antrum would result in lessening of the release of somatostatin. To date, nobody has been able to successfully document changes in physiologic circulating somatostatin levels. The best evidence that makes it unlikely that somatostatin participates in the response is the fact that both the banded gastroplasty and the Roux-Y gastric bypass provide exactly the same alteration, the rapid resolution of the diabetic phenomenon. Since somatostatin is abnormally released in one circumstance and not in the other, antral exclusion certainly does not yield the mechanism.

I believe the phenomenon is probably a matter of resolution of the abnormal insulin resistance. As a result of the correction of insulin resistance, which has been shown to occur rapidly, basal levels of insulin return to normal, and insulin no longer participates in vicious negative feedback inhibition. As a result of these changes, insulin responsiveness returns to normal.

I believe the key phenomenon is the change in insulin resistance, and when we understand why this occurs, I believe we will understand more about this phenomenon.

DR. LEON MORGENSTERN (Los Angeles, California): Dr. Pories, I would like to ask if there were any accidental splenectomies in this large series, and if so, was there any relation to early or late sepsis?

DR. WALTER J. PORIES (Closing discussion): First I would like to thank each of the discussants and, obviously, thank Dr. Mason for having the idea in the first place.

We agree that a comparison between the gastric bypass and the vertical banded gastroplasty offers the elegant experiment to test the effect of the antral and duodenal hormones on glucose metabolism, especially if insulin function and resistance are measured with the rigorous methodology of the insulin clamp. Accordingly, we plan to perform this prospective comparison in the near future and will begin as soon as we have the approval from our institutional review board.

Dr. Woodward, I cannot explain why your number of marginal ulcers is higher than ours (8/397; 2.1%). The use of cimetidine has made it possible to manage these without surgery; we believe that this is a major breakthrough.

I stand in awe of Dr. Jaffe and I have for some time. His speculations are exciting and I hope that he will share his ideas with us during the planning of our next studies.

As Dr. Morgenstern guessed, we have had splenic injuries. There have been 10 (2.6%) in this series and most of these occurred during the first 2 years. Increased experience has helped to diminish this complication.

Comparison of Whole Pancreas and Pancreatic Islet Transplantation in Controlling Nephropathy and Metabolic Disorders of Diabetes

MARSHALL J. ORLOFF, M.D., CELIA MACEDO, M.D., ARTUR MACEDO, M.D., and GLENN E. GREENLEAF, B.S.

To compare the long-term effectiveness of whole pancreas transplantation and pancreatic islet transplantation in controlling the metabolic disorders and preventing the kidney lesions of alloxan diabetes, metabolic and morphologic studies were performed in four groups of rats: (1) NC-116 nondiabetic controls; (2) DC-273 untreated alloxan-diabetic controls; (3) PDT-182 rats that received syngeneic pancreaticoduodenal transplants not long after induction of diabetes with alloxan; and (4) IT-92 rats that received an intraportal injection of at least 1500 and usually 2000 syngeneic pancreatic islets soon after induction of diabetes with alloxan. Each month for 24 months after diabetes was well established, body weight and plasma concentrations of glucose and insulin were measured, and five lesions were scored by light microscopy in 50 glomeruli and related tubules in each kidney by a "blind" protocol: glomerular basement membrane thickening, mesangial enlargement, Bowman's capsule thickening, Armanni-Ebstein lesions of the tubules, and tubular protein casts. There were progressive and highly significant increases in the incidence and severity of all five kidney lesions in the diabetic control rats compared with the nondiabetic control rats. No significant differences were found between the kidneys of Group PDT and those of Group NC, demonstrating that whole pancreas transplantation prevented all of the diabetic kidney lesions throughout the 2-year study period. In contrast, within 3–9 months after pancreatic islet transplantation and thereafter, the incidence and severity of the five diabetic kidney lesions were similar in Group IT and Group DC. Whole pancreas transplantation produced precise metabolic control of diabetes throughout the 24 months of study, whereas pancreatic islet transplantation did not accomplish complete metabolic control, particularly beyond the first several months after transplantation. The difference in the completeness of metabolic control achieved by the two types of transplants is the most likely explanation for their sharp difference in effectiveness in preventing diabetic nephropathy.

From the Department of Surgery, School of Medicine, University of California, San Diego, California

MANY RECENT STUDIES have established that insulin-dependent diabetes mellitus (IDDM) is caused by destruction of the beta cells of the pancreatic islets in a genetically susceptible subject.[1-7] Considerable evidence suggests that the metabolic disorders resulting from loss of beta cells in IDDM are the underlying cause of the progressive secondary complications that develop in the kidney, eye, nervous system, and vasculature. Standard therapy of IDDM with insulin injections and diet has not prevented these secondary complications, presumably because of failure to precisely control the metabolic disturbances.[8-10] Consequently, there is great interest in various types of endocrine pancreas replacement therapy, based on the hope that such treatment will restore physiologic beta cell function and strict metabolic control. However, it is not yet known if any form of endocrine pancreas replacement therapy is capable of preventing, stabilizing, or reversing the lesions of IDDM.

Diabetic kidney disease is the most common cause of death in IDDM, and currently is the most frequent diagnosis in patients who have kidney transplantation or chronic hemodialysis in the United States.[11] Rats with diabetes mellitus (DM) induced by chemical agents that destroy the beta cells of the islets of Langerhans, such as alloxan and streptozotocin, develop renal lesions that appear similar to those found in patients with IDDM, particularly glomerular capillary basement membrane thickening and mesangial enlargement.[12-20] The alloxan diabetic rat, therefore, is a suitable animal model in which to evaluate the effectiveness of therapy on diabetic nephropathy.

Currently, three forms of endocrine pancreas replacement therapy are undergoing intensive investigation: (1) artificial insulin delivery devices; (2) transplantation of

islets of Langerhans; and (3) transplantation of the whole pancreas or a segment of the pancreas as a vascularized graft. Artificial insulin delivery devices have not arrested the progression of or reversed diabetic nephropathy, retinopathy, or neuropathy in the few clinical studies that have been reported to date, perhaps because these devices do not achieve strict metabolic control.[21-32] There have been no studies in humans of the long-term effectiveness of either pancreatic islet transplants or whole pancreas transplants in controlling the metabolic disorders and secondary complications of IDDM, and few studies in animals. Moreover, no studies have been performed comparing the effects on any aspect of diabetes of islet transplants and whole pancreas transplants. Therefore, the current investigation was done to compare, in the same research laboratory, the long-term effectiveness of the two types of pancreas transplantation in providing strict metabolic control and preventing kidney lesions in highly inbred rats with alloxan diabetes over 2 years.

Methods

Experimental Groups

Six-month-old, highly inbred Lewis strain rats (Simonsen Laboratories, Gilroy, CA), which uniformly accept tissue transplants from each other without rejection, were housed two to five to a cage and fed standard rat chow and water *ad libitum* throughout the study. The animals were distributed among four groups as follows: (1) *Group NC* (nondiabetic control) contained 116 unaltered rats. (2) *Group DC* (diabetic control) contained 273 untreated diabetic rats in which DM was induced by intravenous injection of alloxan monohydrate (Sigma Chemical Co., St. Louis, MO) in a dose of 42–44 mg/kg. For acceptance into the study, rats were required to have plasma glucose levels that were above 200 mg/dL on both the third and seventh days after alloxan injection. Most rats had plasma glucose levels above 300 mg/dL. (3) *Group PDT* (pancreaticoduodenal transplant) contained 182 rats that received a heterotopic pancreaticoduodenal isograft from an age-matched donor rat 1 week after DM was established by the same method used in Group DC. (4) *Group IT* (islet transplant) contained 92 rats that received 1500–2000 syngeneic pancreatic islets from age-matched donor rats by injection into the portal vein 1 week after DM was established by the same method used in Group DC.

Every month for 24 months after onset of DM, two to four rats from each group were killed for quantitative morphologic studies of kidney pathology. Since the measurements of kidney lesions spanned from age 7 months to age 30 months, and the normal life span of the Lewis rat in our laboratory usually ranges from 24–30 months, the studies of diabetic nephropathy extended over nearly the entire life span of the rats.

Technique of Whole Pancreas Transplantation

In 1971, we devised the microvascular surgical technique of heterotopic pancreaticoduodenal transplantation in the rat.[33,34] The pancreaticoduodenal graft was harvested from the donor rat with a segment of aorta containing the celiac and superior mesenteric arteries supplying the graft, and with a segment of portal vein containing the venous drainage from the graft. The pancreaticoduodenal graft was transplanted into the recipient rat by performing end-to-side vascular anastomoses with continuous 9-0 nylon sutures between the graft aortic segment and the host aorta, and between the graft portal vein segment and the host inferior vena cava. The proximal end of the graft duodenum was closed and the distal end was anastomosed to the side of the third portion of the host duodenum using a continuous 7-0 silk suture. Graft ischemia time was 25 ± 5 minutes.

Technique of Pancreatic Islet Transplantation

Pancreatic islets were obtained from 10–12 donor rats by the collagenase digestion method of Lacy and Kostianovsky.[35] The common bile duct was perfused with Hanks solution to distend the pancreas and disrupt the acinar tissue, and the pancreas was removed and minced into fine fragments with scissors. The pancreatic fragments were digested with collagenase (Sigma Type V, Sigma Chemical Co., St. Louis, MO) in a shaker water bath and serially washed and centrifuged. The islets were separated from remaining acinar tissue by Ficoll gradient centrifugation, which was followed by serial washing and centrifugation. The number of islets in an aliquot of the pool was counted under a microscope. The pool of fresh islets was placed in a syringe and injected immediately into the portal vein of a diabetic recipient rat through a 25-gauge needle. Each recipient received an intraportal injection of at least 1500 islets, but the vast majority of recipients were given approximately 2000 islets.

Metabolic Studies

All rats had metabolic studies done. Monthly measurements were made of body weight and plasma concentrations of glucose and insulin. Intraperitoneal glucose tolerance tests were done monthly. Plasma glucose was measured by a modification of the O-toluidine method and plasma insulin was measured by a specific double antibody radioimmunoassay. All blood specimens were obtained from the rats' tail vein between 9:00 A.M. and 10:00 A.M., and the animals were not fasted.

The detailed results of the metabolic studies will be the subject of a separate report.

Morphologic Studies of Kidney Lesions

Kidney tissue obtained at autopsy each month for 24 months was fixed in 10% buffered formalin, embedded in paraffin, cut into sections 4-μ thick, and stained with hematoxylin and eosin, Mallory's trichrome, and periodic acid-Schiff stains. The sections were coded to mask their identification by the examiner and eliminate observer bias, and the code was not broken until the study was completed. Fifty glomeruli and the related tubules from each kidney were examined by light microscopy without knowledge of the group from which the tissue had been obtained, and the following five lesions were scored on a scale of 0 (absent), 1 (mild), 2 (moderate), and 3 (severe): glomerular basement membrane thickening (GBMT), mesangial enlargement (ME), Bowman's capsule thickening (BCT), Armanni-Ebstein lesions of the tubules (A-E), and tubular protein casts (PRO). The scores for each lesion were expressed as a total count per rat by adding the individual scores for each glomerulus and related tubules. Morphologic studies of kidney lesions were performed in 63 rats in Group NC, 104 rats in Group DC, 91 rats in Group PDT, and 92 rats in Group IT.

Statistical Analysis

A two-tailed Student's t-test was used to examine differences between mean values.

Results

Metabolic Studies

Table 1 shows the results of serial measurements of body weight. Untreated diabetic control rats (Group DC) did not gain weight throughout the 2-year study period. Pancreaticoduodenal transplants were significantly more effective than pancreatic islet transplants in stimulating weight gain and growth in diabetic rats ($p < 0.001$ from the 6th to the 24th months between Group PDT and Group IT). After the 20th month, mean body weights in Group IT and Group DC were not significantly different.

Table 2 shows the mean plasma glucose levels in the four groups of rats. The untreated diabetic control rats (Group DC) had plasma glucose levels that were three times those found in the nondiabetic controls (Group NC) ($p < 0.001$). Pancreaticoduodenal transplantation (Group PDT) reduced the diabetic plasma glucose levels to normal and maintained strict metabolic control throughout life. Mean plasma glucose concentrations in the rats with whole pancreas transplants were not signifi-

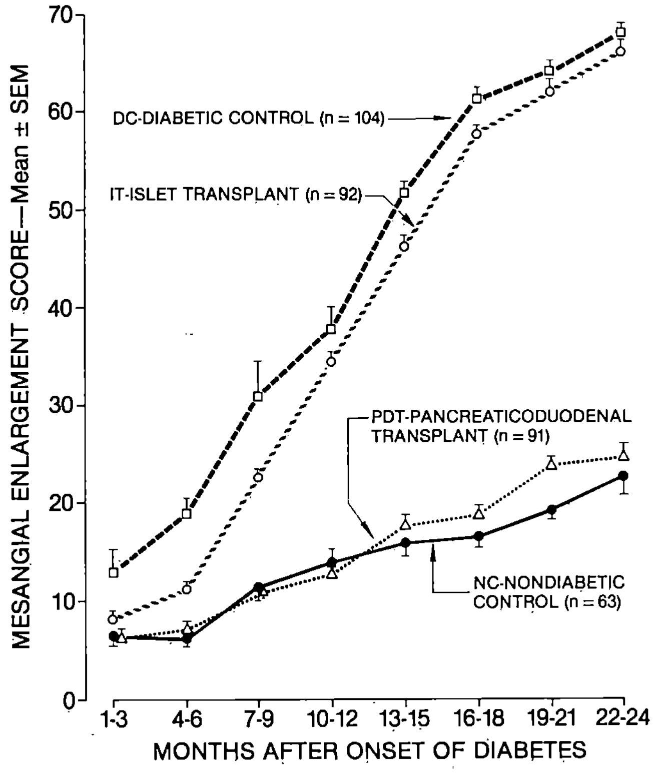

FIG. 2. Mean scores of mesangial enlargement in the four groups of rats.

cantly different from those in the nondiabetic controls. Pancreatic islet transplantation (Group IT) also produced a reduction of plasma glucose levels to the normal range during the first 2 months. However, from the third to the 24th months after induction of DM, mean plasma glucose concentrations in Group IT were significantly higher than those in the nondiabetic controls ($p < 0.001$), although the levels were well below those found in the diabetic controls.

Table 3 shows the results of monthly assays of plasma insulin. Mean plasma insulin concentrations in the untreated diabetic controls were depressed to 18–28% of the concentrations found in nondiabetic controls, but were restored permanently to normal or above by whole pancreas transplantation. On the other hand, although pancreatic islet transplantation restored plasma insulin levels to normal for the first 6 months of the study, there was a significant and progressive decline in plasma insulin concentrations below the normal range after the sixth month ($p < 0.001$).

Quantitative Morphologic Studies of Kidney Lesions

Glomerular basement membrane thickening (GBMT). Figure 1 shows the mean scores of glomerular capillary basement membrane thickening in the four groups of rats. In the nondiabetic controls, there was a gradual and progressive increase of GBMT during the 24 months of the study. GBMT in the untreated diabetic controls was significantly greater than in the nondiabetic controls at every time interval ($p < 0.001$), and the rate of increase was more rapid. Pancreaticoduodenal transplantation prevented abnormal GBMT. Mean scores in Group PDT were not significantly different from those in Group NC at any time. Pancreatic islet transplantation did not prevent the abnormal GBMT associated with DM. At all time intervals, mean scores of GBMT in Group IT were significantly greater than in Group NC ($p < 0.001$), but were not significantly different from those in Group DC.

Mesangial enlargement. Mean scores of mesangial enlargement in the four groups of rats are shown in Figure 2. As with GBMT, there was gradual ME over 24 months in the nondiabetic controls. Pancreaticoduodenal transplantation produced ME scores that were not significantly different from those found in Group NC. In contrast, beginning after 3 months of untreated DM, there was highly significant ME compared with that found in nondiabetic rats ($p < 0.001$), and pancreatic islet transplantation did not slow the rate at which ME developed. Mean scores of ME in Group IT were abnormal after the third month of the study, and were not significantly different from those in Group DC after the ninth month.

Bowman's capsule thickening (BCT). Figure 3 shows the mean scores of Bowman's capsule thickening in the four groups of rats. BCT was highly abnormal in the diabetic controls compared with that of the nondiabetic controls at all time intervals ($p < 0.001$). Pancreaticoduodenal transplantation prevented abnormal BCT throughout the 24-month study period. Pancreatic islet transplantation did not slow the rate of BCT associated with DM. Mean scores in Group IT were not significantly different from those in Group DC.

Armanni-Ebstein Lesions (A-E). Figure 4 shows the mean scores of A-E lesions, which consist of vacuolization and distention of the cells of the renal tubules, presumably due to glycogen accumulation.[20,36] No A-E lesions were found in normal control rats until 16–18 months, and few lesions were seen thereafter. Similarly, no A-E lesions were found at any time in rats with pancreaticoduodenal transplants. In contrast, there was a progressive increase in A-E lesions over 24 months in both the diabetic controls and the rats with islet transplants. After the sixth month, there were no significant differences in mean A-E scores between Group IT and Group DC.

Tubular protein casts (PRO). Figure 5 shows the mean scores of PRO in the four groups of rats. Normal control rats did not have any PRO until 10 months after entry into the study and then had a small but progressively increasing incidence of this abnormality. Mean scores of PRO in rats with pancreaticoduodenal transplants were not significantly different from those in normal control rats at any time. Untreated diabetic controls had a significant number of PRO at 1–3 months, and mean scores of PRO increased progressively over the 24 months of study. Islet transplantation did not prevent PRO; mean scores of PRO in Group IT and Group DC were not significantly different after the sixth month.

Discussion

Previous studies in our laboratory demonstrated that syngeneic pancreaticoduodenal transplantation performed soon after induction of alloxan diabetes in young rats, produced precise, life-long control of the metabolic disorders of DM.[37] Severe DM recurred when the pancreas graft was removed after 1–2 years. Furthermore, in quantitative morphologic studies conducted according to a "blind" protocol, we found that abnormal GBMT[38] and ME[39] in the kidney of alloxan-diabetic rats were prevented for life by whole pancreas isografts. Additionally, in quantitative morphologic studies completed recently, we observed that whole pancreas transplants performed at any time from 6–21 months after induction of alloxan diabetes were consistently capable of reversing severe ME.[40] No other long-term met-

abolic studies or quantitative morphologic studies involving whole pancreas transplantation have been reported. Metabolic and morphologic investigations are being conducted in patients with IDDM who have had whole pancreas transplantation,[41] but the results are inconclusive because of short periods of observation and the small number of subjects available for study.

The results of the current investigation confirm and extend our previous observations with regard to whole pancreas transplantation. Pancreaticoduodenal isografts produced tight metabolic control for life and prevented all of the major kidney lesions of DM for 2 years. The kidney of diabetic rats that received pancreaticoduodenal transplants was not different in any respect from the kidney of age-matched nondiabetic controls.

In contrast to the paucity of work on whole pancreas transplantation, a number of studies have been reported of the effects of pancreatic islet transplantation on kidney lesions in rodents with chemical DM.[42–56] However, these studies have been short-term investigations conducted in a small number of animals, and only six have used quantitative morphologic methods and a "blind" protocol. One of these six quantitative studies reported prevention of GBMT in mice 6 months after islet transplantation,[51] and one study showed reversal of ME in rats 2 months after islet transplantation.[52] The other four quantitative studies reported failure of islet transplants to prevent[49] or reverse[50–52] either ME or GBMT.

The results of the current investigation indicate that pancreatic islet transplants were not capable of preventing the kidney lesions of DM. These findings are in accord with those of the majority of other investigations that used quantitative morphologic methods. Although the scores of the kidney lesions in rats with islet transplants were similar initially to those in the nondiabetic controls, beginning 4 months after transplantation and thereafter the scores in Group IT were significantly higher than those in Group NC ($p < 0.001$). Within 3 months after islet transplantation and thereafter, the severity of GBMT and BCT was similar to that found in diabetic controls, and within 6–9 months the severity of the other three lesions was similar in Group IT and Group DC. These results are in striking contrast to those obtained in rats with whole pancreas transplants.

The most likely explanation for the sharp difference in effectiveness between pancreaticoduodenal transplants and pancreatic islet transplants lies in how completely the two forms of transplantation achieved metabolic control. Whole pancreas transplantation accomplished precise metabolic control, manifested by continuously normal plasma glucose concentrations and normal or greater than normal plasma insulin levels. On the other hand, although islet transplantation produced normal plasma glucose levels for the first 2 months and substantially reduced hyperglycemia for life, plasma glucose concentrations were persistently abnormal after the third post-transplant month. Moreover, plasma insulin levels were subnormal after the sixth post-transplant month. Islet transplantation did not achieve complete metabolic control despite injection into the portal vein of 2000 islets, a dose that is considerably larger than that used by many other investigators.[57]

Improved but incomplete metabolic control has been a consistent finding in the short-term studies of pancreatic islet transplantation reported by other workers.[42,45,51,55,56,58–63] Specifically, normoglycemia was not achieved in a substantial number of animals with islet transplants, and those that were normoglycemic initially often had recurrence of hyperglycemia within 3–12 months. Moreover, plasma insulin levels consistently remained below normal, and the results of oral and intravenous glucose tolerance tests did not return to normal. Thus, even in short-term studies, pancreatic islet transplantation has not achieved precise metabolic control.

The same is true of artificial insulin delivery devices.[64,65] In patients with IDDM, insulin pump therapy has been shown to lower plasma concentrations of glucose and to correct abnormalities of amino acids, lipids, catecholamines, and growth hormone, but it has not accomplished long-term normoglycemia.[64,65] A number of recent studies have reported progression of nephropathy[21–23] and retinopathy,[24–32] and failure to improve neuropathy[32] during insulin pump therapy, perhaps because metabolic control has not been sufficiently precise to reverse the diabetic lesions.

The development and progression of diabetic nephropathy have not been prevented by conventional treatment with insulin injections and diet.[8–10] Nephropathy often develops in normal kidneys transplanted into diabetic recipients for end-stage renal failure, despite concerted efforts at metabolic control with conventional therapy.[66–69] Our previous findings that whole pancreas transplantation is capable of preventing GBMT and ME, and our current demonstration that pancreaticoduodenal transplants are effective in preventing all renal lesions of experimental DM, suggest that whole pancreas transplantation may be indicated in patients with end-stage diabetic nephropathy who require kidney transplantation and, therefore, must be given immunosuppression therapy for life. The outlook for the usefulness of pancreatic islet transplantation appears less promising.

Acknowledgments

We thank Hazel J. Sayers and Sun Lee for technical assistance with the transplantation operations.

Discussion

Dr. John S. Najarian (Minneapolis, Minnesota): I want to congratulate the author on a very nice presentation of studies that we have followed with interest over the years.

I am, at one point, however, concerned about the conclusions that Dr. Orloff has reached. Therefore, I would like to state a few facts and ask a couple of questions.

In 1974, in the journal *Diabetes,* we showed that syngeneic islets, when transplanted to rats, can prevent, as well as reverse, the lesions of experimental diabetes in the kidney. This finding was reported in a syngeneic rat system in which the recipient rat was made diabetic with streptozotocin, a different form of beta cell poison than alloxan. This reversal was complete for diabetic lesions, which occurred within 3 months of streptozotocin treatment. However, if we waited 6–9 months, we could not reverse the lesions, which now became collagen-filled and irreversible. In its early and proliferative stages, however, the mesangial matrix material, which is the *sine qua non* of this lesion, could be reversed.

In 1975, armed with this information, we progressed to treating 20 patients who were Type I diabetics with allogeneic islets. We transplanted them with what we believed were enough islets, and yet, in each instance, we were only able to reduce their insulin requirements but never cure a single patient (insulin independence).

We temporarily gave up on this technique and went back into the clinical arena to perform segmental organ transplantation of the pancreas, as we had done initially in 1966 with whole organ pancreaticoduodenal transplants. Since 1978, we have performed 185 segmental or whole organ pancreas transplants.

At the same time we were puzzled with what happened to the transplanted islets in the previous clinical series. Was it a fact that we did not technically transplant viable islets, or was the lack of success due to immunologic rejection?

To determine which phenomenon was responsible for this failure, we investigated a series of patients with chronic small duct pancreatitis. We removed their pancreases, isolated the islets, and gave them back their own (autologous) islets, so there could be no immunologic consequences.

Under those circumstances, even though the number of islets was limited, half of these patients did not require further insulin, and currently, we have seven patients on isolated autogenous islets transplanted to the liver who do not require insulin and have excellent metabolic control. Our technique, therefore, was good; therefore, there must be immunologic problems that need to be solved to make islet allotransplantation successful.

Dr. Sutherland and I then went on and did 185 pancreatic organ transplants, whose results we presented to this Association, and clinically 60% of these transplants have worked very well. With pancreas transplants, we have seen partial reversal of triopathy; the renal lesions, the retinal lesions, and the neurologic lesions.

It is tempting to hope that the islets would work because, in fact, it would involve less surgery. In addition, you have enough islets so that you could treat more than one patient with the islets obtained from a single cadaveric donor.

It has been shown by various groups that you can transplant islets and achieve a completely normal glucose tolerance curve. This has been shown by David Sharp in St. Louis, Gus Nossal's group in Australia, Conrad Federle in Germany, and John Paul Squifflet in Brussels. All of these investigators have shown that with islets they can get normal glucose tolerance curves and can prevent the lesions that Dr. Orloff observes with animals that receive pancreatic transplants.

Thus, what has happened in the Orloff experiment with islet transplantation? We have found that when you put islets into the liver you lose about half of them. Therefore, we increased the number of islets transplanted sufficiently enough to get equivalent numbers of islets to those that we transplanted with whole organ pancreas transplants.

When we did that, there was no difference between the results of pancreatic organ transplants and islet transplants.

My question to Dr. Orloff is: how did you measure the amount of islets or insulin content that you had in the liver? In addition, even the slightest bit of species difference with islets would show the kind of erosion that he reported with the loss of islets with time. What species did you use and what combinations?

Dr. Keith Reemtsma (New York, New York): The question posed by Dr. Orloff is of central importance, and in his studies, islet transplants do not work well. However, other investigators have found that islet transplants can, in the long run, produce normal metabolism and reversal of the vascular diabetic changes, as measured by renal function and morphology.

The important question here is why, under the circumstances of this study, islet transplants do not function well. I would agree with Dr. Orloff that the most likely explanation for the vascular changes is the incomplete reversal of the metabolic state. But why? The pattern of failure suggests an inhospitable environment for the transplanted islets. Perhaps Dr. Orloff could comment on the liver pathology, as alloxan produces periportal fibrosis, and this might interfere with islet function.

These studies confirm that whole pancreas grafting is effective, and it results in hyperinsulinemia. The eventual role of islet transplants, however, remains unanswered.

Dr. Robert J. Corry (Iowa City, Iowa): I compliment Dr. Orloff on an excellent paper regarding an important issue; that is whether or not successful pancreatic transplantation can prevent or stabilize the devastating secondary complications of Type I diabetes. In his study, rats who received islets did not achieve normal glucose control, suggesting either that an insufficient supply of islets was administered or something happened to them in the first few months, such that normal glucose control could not be achieved. On the other hand, whole organ pancreatic transplantation resulted in normal glucose metabolism and prevented complications.

With regard to whole organ grafting we have reasons to be optimistic as a result of evidence emerging from a few U.S. and European pancreas transplant programs. In Stockholm, Carl Groth has shown prevention of the mesangial thickening in the glomeruli in patients who received combined kidney and pancreas grafts compared with another group of patients transplanted at the same time, namely diabetic recipients who received kidneys only. All patients who received kidneys and were followed after 3 years had microscopic changes of diabetes in the glomerulus, whereas none of the patients who received combined kidneys and pancreases had any degree of mesangial thickening.

In addition, Walter Land in Munich has shown some evidence of reversal of neuropathy as well as vasculopathy. Donald Dafoe in Michigan has presented some interesting data showing that blood lipids are significantly lowered in patients who have received successful pancreas grafts.

I would like to show a few slides indicating that whole organ transplantation of the pancreas does not necessarily preclude successful liver donation. This illustration shows the blood supply of both organs dissected. Essentially the gastroduodenal artery is ligated and the splenic artery is divided a few millimeters from its origin on the hepatic artery. The superior mesenteric artery is divided near the pancreas. The portal vein is divided as it exits the pancreas. In this way the blood supply for the donated liver will be normal, namely the aortic patch and entire portal vein go with the liver. Extension grafts are placed on the pancreas under ice by taking a segment of donor iliac artery with both branches. The internal iliac artery is then joined to the superior mesenteric artery and the external iliac artery is joined to the splenic artery. Donor iliac vein is then used to extend the portal vein. These extension grafts are placed under iced solution so the ischemic time is not extended very much.

Dr. Thomas E. Starzl (Pittsburgh, Pennsylvania): This is a grand organization that we belong to and the prestige of the organization is so great that a paper presented here is apt to be construed as the last word. If we really accept this paper on absolutely face value, this could be the death knell of islet cell transplantation. It is in that context that I want to make a few comments and this is where I am inclined to be in agreement with Dr. Najarian.

Solid pancreas transplantation in principle as practiced successfully by Dr. Orloff and by others at Minnesota and elsewhere, is different than almost anything else we do. If we transplant the kidney, there is no carrier tissue that comes along with the graft. It is a simple, straightforward intellectual exercise. If there is any carrier function that comes with the kidney, it might be the production of erythropoietin. The heart is a simple pump, and with the liver, practically every cell does something that is essential for the survival and health of the recipient. In the case of the pancreas we are transplanting an organ in which if we transplant 100 g, almost all of that is tissue, which, first of all, is not needed, and second, is a nuisance. That extra tissue accounts for almost all the morbidity and mortality of whole organ pancreas transplantation, which is considerable.

What are the options? One of the options is the procedure that fared so poorly in Dr. Orloff's comparison. I do not doubt for a moment his conclusions, but I must say that I still have hopes for islet cell transplantation. I hope that this paper, as fine as it is, will not cause funding to be precluded for islet cell research or efforts to be stopped by some of those groups that are still making those efforts such as Scharp in St. Louis, Lafferty and Weil from Colorado, Mintz and Miller from Miami, and possibly others including Sutherland of Minnesota and Barker et al. from Pennsylvania.

Other options have to be carefully explored because of the deficiencies not only of whole organ transplantation, but also of islet cell transplantation. One possibility might well be gene splicing, in which cells are endowed with the ability to produce insulin. Anything that could move us in that direction would be valuable and certainly would be worth pursuing.

The annals of history, as my friend, Mark Ravitch, has reminded me often, are replete with missed opportunities. I could recount many but these would reveal my age. We do not have to go much farther back than last month's *New England Journal of Medicine* in which there was a report from Mexico about successful transplantation of adrenal tissue into the brain for the treatment of neuropsychiatric disorders. This was a procedure that had been thoroughly discredited in previous Scandinavian trials, but that now holds great promise instead. I hope that islet transplantation or some analogue or derivative of that procedure is not actually dead.

DR. MARSHALL J. ORLOFF (Closing discussion): I am honored to have this work discussed by some of the giants in this field, and there is no doubt that they are the giants. Keith Reemtsma was working on pancreas transplantation when I was just a boy, and he reminded me of that before he got up to discuss my paper. He has made enormous contributions to this field. As to John Najarian, whenever I present a paper, he always gets up and says: "It is a very nice piece of work, but we did that back in 1970." And he is sometimes right. His experimental and clinical work and that of his group, David Sutherland and the others, has been monumental in the field of pancreas transplantation. I guess you would have to call the Minnesota group the leading pancreas transplantation group in the world. Of course, I cannot even begin to describe what Tom Starzl has done for everything in transplantation. It is awesome. I hate to think about it because I feel so inferior after thinking about all the things that he has done. Rob Corry is a relative newcomer, the new kid on the block, but the results that they are having in Iowa with clinical transplantation of the pancreas are extremely promising and they have developed very rapidly. They certainly have my respect.

The main issue I believe, and it is a critical issue, is what degree of metabolic control is required to prevent and/or reverse the lesions of diabetes, not just in the short term, but in the long term. Our experimental data suggest, and in fact the clinical data including the data on insulin pump therapy suggest, that the control must be very precise and must be of long duration. Brief periods of control for a few months do not really mean a lot. It has to be very precise and prolonged.

As far as we can tell, at least to this point, the most precise metabolic control comes from transplanting the whole pancreas. It is the only form of endocrine pancreas replacement therapy that has produced complete and prolonged metabolic control.

Regarding the comments of John Najarian, I have the following response: (1) The 1974 report of his group in *The Journal of Experimental Medicine*, in which kidneys from 11 diabetic rats were transplanted into normal rats, did not show statistically significant reversal of mesangial matrix thickening. Furthermore, this was a very short-term, nonquantitative study in which the kidneys were transplanted after only 6 months of diabetes and then were studied only 2 months later. I do not believe any conclusions from this study, positive or negative, are possible. (2) As to his six patients who have received autologous islets, the problem with all of these case reports is that the patients have not had long-term, well-established diabetes before islet transplantation, and there is always the question of whether the patients would have had diabetes without the autologous islet transplantation. The hard facts are that there is not a single case of successful, prolonged relief of diabetes mellitus among the more than 100 diabetic patients who have received islet transplants. (3) Regarding John's statement that many have shown completely normal GTT's following islet transplantation, the facts are that if one examines the literature carefully, one will be hard-pressed to find *long-term*, clearly documented normalization of the GTT. For example, Renold's group and Barker's group both found that the GTT remained abnormal, and numerous studies, including those from Dr. Najarian's own institution (Steffes et al., Vialettes et al.) have shown failure of plasma glucose and insulin levels to normalize both initially and in the long term. (4) John asked: Is it possible that our islets were being rejected? We used highly inbred Lewis rats. We have shown that these rats accept transplants of skin, whole pancreas, liver, intestine, stomach, spleen, and heart without developing clinical or histologic evidence of rejection. There was no histologic evidence whatsoever of immunologic rejection of our islet transplants. (5) Finally, Dr. Najarian asked how we measured the volume of islets transplanted. We counted the number of islets microscopically in an aliquot of the islet suspension. We transplanted approximately 2000 islets, which is more than the number used by the vast majority of workers. For example, in intraportal transplants, Kipnis, Lacy et al. used 350–1000 islets, Barker et al. used 400–500 islets, and Federlin et al. used 500–800. There is no question that our transplants were successful, since they produced normal plasma glucose and insulin levels for the first several months. Measurement of insulin output from the liver is not a good way of quantitating the adequacy of the transplant, unless repeated measurements over a long period are made, and no one has done that.

Keith Reemtsma raised the possibility that alloxan might cause periportal fibrosis that interferes with the viability of the islets. We have studied several thousand rats with alloxan diabetes and have never seen any evidence of periportal fibrosis or hepatic changes. Moreover, our islet transplants were very viable for the first several months. However, as others such as Barker et al. have observed in streptozotocin diabetes, there is a progressive loss of islets after initial metabolic control, I believe because they do not bring their own supply of blood vessels and have a very tenuous existence. As time goes by, the islets are easily lost, perhaps as a result of even transient reductions in hepatic blood flow and oxygen supply.

Tom Starzl made an inspirational statement about continued funding for research in islet transplantation. I do not believe there is anything to fear. Having worked in the field of portal hypertension for many years, I have often observed that nothing dies except the patients.

Although I have considerable doubt about the ultimate success of islet transplantation, there is no question that continuing research is warranted along all avenues that could conceivably help the millions of patients who suffer from diabetes. Moreover, islet transplants have provided and will continue to provide important information about many aspects of diabetes and its treatment. An understanding of islet physiology, islet immunology, and prevention of islet rejection are but a few of the potential and actual benefits of islet transplant research.

CLASSIFIED AD SECTION

Classified advertising is available in **ANNALS OF SURGERY** for those recruiting personnel or interested in obtaining positions. Display space also is available for those desiring greater visibility or more space for their message.

Classified ad copy, like other advertising copy, will be reviewed for approval prior to publication.

Classified Rates: $9.00 per line or fraction of line. The average line will be 40 characters.

Box Numbers: Replies may be directed via Box # to J.B. Lippincott Company, at an extra charge per insertion of $6.50 to cover handling costs in forwarding such replies to the advertiser.

How to Order: Send typewritten text copy for the ad with remittance in full to:

ANNALS OF SURGERY
c/o J.B. Lippincott Company
Attn: Dorothy Glover
East Washington Square
Philadelphia, Pa. 19105
(215) 238-4215

Deadline: Copy received by the 15th of month will run in the second following month's issue, e.g. November 15th for January issue. Ads received after the 15th will run in the next available issue.

BC/BE general surgeon to join expanding department in multispecialty group practice serving FFS and prepaid patients in Central Massachusetts. Practice in university-affiliated hospitals with opportunities for clinical research. Send CV to **Medical Director, Fallon Clinic, 630 Plantation Street, Worcester, Massachusetts 01605.**

CHIEF OF DIVISION OF GENERAL SURGERY, BOSTON AREA: Seeking an individual qualified for appointment at the Associate Professor level to serve as Chief of General Surgery and academic liaison in a Boston area teaching hospital university program. Professional skills in surgical oncology are preferred. Salary will be commensurate with experience. Send CV in confidence to **Box ANN9A, J.B. Lippincott Co., East Washington Square, Philadelphia, PA 19105.**

CHIEF OF SURGERY—A major affiliate of the University of Minnesota is inviting applications for Chief of Surgery. Qualifications: Board certified in General Surgery; established record of scholarly achievement and commitment to excellence in teaching, research, and clinical service; demonstrated management and leadership skills including fiscal affairs; ability to direct a fully accredited residency in General Surgery and to coordinate educational and service programs with other surgical and non-surgical specialties and with the University of Minnesota. Candidate must be eligible for appointment to Senior Faculty of the University of Minnesota. Affirmative Action Employer. Specifically invites and encourages applications from women and minorities. Address inquiries with CV to: **Phillip Peterson, M.D., Chairman, Surgery Search Committee, Hennepin County Medical Center, 701 Park Avenue, Minneapolis, MN 55415.**

COLORADO PERMANENTE MEDICAL GROUP is an expanding multispecialty prepaid group practice caring for members of the Kaiser Foundation Health Plan. Position available immediately for BE/BC general surgeon to join existing eight man department. Competitive salary and benefits. Contact: **Toby Cole, M.D., Executive Medical Director, Colorado Permanente Medical Group, P.C., 2045 Franklin Street, Denver, CO 80205.** EOE M/F handicapped/veterans.

DIRECTOR OF TRAUMA and SURGICAL CRITICAL CARE: Selected applicant will be Director of Trauma and Surgical Critical Care, responsible for developing clinical and laboratory projects pertaining to these areas. Additionally, the director will be heavily involved with both clinical responsibilities and graduate surgical education of surgical residents in our fully approved residency program. **QUALIFICATIONS:** Graduate of an A.A.M.C. approved medical school, board eligibility/certification in surgery, fellowship in trauma with extensive critical care experience. Documented experience in clinical and laboratory research. Salary guarantee and extensive benefits. **REPLY TO: Helmut Schreiber, M.D., Chairman, Department of Surgery, Huron Hospital, 13951 Terrace Road, Cleveland, OH 44112.**

EXPERIENCED GENERAL SURGEON needed to step into busy established practice with multi-specialty group. Successful candidate must be Board Certified/Eligible and have some training or expertise in Vascular Surgery. Package includes $80,000 first year salary, plus productivity and complete benefits. Full partnership after one year. Located in lovely northern Illinois community. Contact: **James Russell, Inc., P.O. Box 427, Bloomington, IL 61702, phone (309) 663-9467.**

GENERAL SURGEON—BC/BE, with broad-based training (especially in areas of trauma, burns, pediatric and non-cardiac thoracic surgery) to join a 38-doctor multi-specialty clinic with three well-established general surgeons. Modern forward looking hospital with excellent staff and superb equipment. Located in a southern Wisconsin college town of 50,000 near Chicago, Milwaukee and Madison. Guaranteed salary initially but optional transition to compensation based on production. Position available for June, 1988 or sooner. Contact: **James F. Ruethling, Administrator, Beloit Clinic, S.C., 1905 Huebbe Parkway, Beloit, WI 53511, Ph. 608/364-2200.**

PLASTIC & RECONSTRUCTIVE SURGEON: 200+ member multispecialty group seeks BC/BE specialist; large primary, secondary, and tertiary practice with substantial referrals; adjacent to 500 bed hospital with superior intensive care unit; free-standing ambulatory surgery center; affiliated with medical school, part time faculty appointments available; located in upper midwest tri-college community of 130,000; 35 minutes from clean lake region; will pay travel expenses for physician and spouse to travel. Send CV in confidence to **Charles B. Anderson, M.D., P.O. Box 2067, Fargo, ND. 58123.**

PEDIATRIC SURGEON: 200+ member multispecialty group seeks BC/BE specialist to join colleague; large primary, secondary, and tertiary practice with substantial referrals; adjacent to 500 bed hospital with superior intensive care units; Pediatric and high-risk nursery, NACHRI designated Children's Hospital; air ambulance & helicopter; affiliated with medical school, part time faculty appointments available; located in upper midwest tri-college community of 130,000; 35 minutes from clean lake region. Send CV in confidence to **Charles B. Anderson, M.D., P.O. Box 2067, Fargo, N.D. 58123.**

We've Corrected Everybody's Flaws. Even Our Own.

And now Weck is ready with the Hemoclip® X20. The first ring-handled automatic ligating clip applier that's as close to perfect as you can get.

But during development, we corrected a lot of flaws we found in competitive disposables, and even in our own first-stage X20 prototype.

Here's the result: the X20's long straight shaft, curved tip and jaws

provide smooth, accurate placement. Jaws are always visible, and they don't retract or jump forward during closure.

There's no cocking a feeder, because the new X20 with clip counter is fully automatic. This truly one-handed disposable virtually eliminates dropped clips.

Contact your Weck representative, and free up some hands in the OR.

The Hemoclip® X20.
The Perfect Way To Apply
A Hemoclip® Clip.

against the *B. fragilis* group?

the facts *still* favor Mefoxin® IV/IM

(Cefoxitin Sodium | MSD)

The *Bacteroides fragilis* group includes *B. fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus.*

The percentages displayed are a weighted average of the susceptibilities reported for these organisms at an MIC breakpoint of 16 mcg/mL by the Antibiotic MIC Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1986,* Totowa, NJ, BAC-DATA® Medical Information Systems, Inc. This average was weighted by the frequency of isolation of each organism.

NOTE: *In vitro* activity does not necessarily imply *in vivo* effectiveness.

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae.* Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

For a Brief Summary of Prescribing Information, please see following page.

MSD

SHARP&
DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST‖ reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage®# vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

Blood Flow in Colonic Anastomoses

Effect of Stapling and Suturing

RAPHAEL S. CHUNG, M.D., F.A.C.S.

From the Departments of Surgery, Veterans Administration Medical Center and State University of New York Health Science Center, Syracuse, New York

Sutureline blood flow was measured with laser Doppler velocimetry in colonic anastomoses created with the stapler, manual suturing, or a combination. Blood flow was always reduced in the sutureline compared with normal mucosa. Of all the anastomoses studied, tight stapling reduced sutureline blood flow the most, whereas the two-layered manual anastomosis or stapling reinforced with sutures were somewhat less ischemic. Stapling adjusted to bowel wall thickness impaired flow only moderately. It was possible with practice to outperform the stapler by single-layered manual anastomosis using fine sutures. In humans, stapled ileocolostomy had a higher sutureline blood flow than the two-layered manual anastomosis. In view of the existing clinical experience of safe stapling without adjustment for bowel wall thickness, a low sutureline blood flow is probably tolerated to a considerable degree in humans. However, this study clearly shows that tight stapling can reduce sutureline blood flow unduly, whereas superior blood supply can be attained by attention to staple closure height relative to bowel wall thickness.

THE BLOOD SUPPLY to the sutureline, believed to be of fundamental importance in healing of anastomoses, is difficult to study because of logistical problems. The tension of suturing, a major variable that affects blood flow, is not easy to standardize. Also, the minute area of the sutureline does not lend itself readily to accurate flow measurements. In this study, stapling is used as a method of suturing at reproducible tension, with staple closure height adjusted according to tissue thickness. Sutureline blood flow is recorded with laser Doppler velocimetry, which provides a continuous recording in real time. By direct application of the fine laser Doppler probe to the narrow rim of tissue inside of the staple lines or on top of the manual sutureline, tissue blood flow of the area in question can be measured with confidence. The model was first tested for validity: the effect of tight stapling on sutureline blood flow was determined by this technique. The effect of manual suturing on anastomotic blood flow was then compared with that of stapling. The methodology was subsequently modified to study ileocolic anastomoses in patients.

Methods

Laser Doppler Velocimetry

The instrument (Laserflo BPM 403, TSI Inc., St. Paul, MN) uses an infrared laser (wavelength 780 nm, output 2 mW) with a penetration depth of 1 mm. The flow probe, 2.2 mm in diameter, contains fine optical fibers that conduct the laser to the tissue and carry the reflected light back to photodetectors. The reflected light undergoes a shift in wavelength due to the Doppler effect, the magnitude of the shift being proportional to the velocity of the red blood cells. To minimize motion artifacts, a holder modified from a micropositioner was used to hold the probe against the tissue at a standardized pressure of 8 g/cm^2. Transmitted respiratory and cardiac motion was reduced by resting the gut on a platform; when movement proved difficult to eliminate, the probe was coupled to the tissue with a miniature suction cup so that the probe and tissue moved together. Motion artifacts were in general recognizable as erratic readings that appeared on tracing as sharp irregular spikes. Duplicate readings were obtained from steady tracings lasting at least several minutes.

The instrument readout was in hertz × 10^2, a frequency measurement. The instrument manufacturer recommends conversion into mL/100 g/min by multi-

* N = 5, mean ± SE.
† MBF vs. SBF, paired t-tests.
‡ *vs.* Group I, unpaired t-tests.

MBF = mucosal blood flow, SBF = sutureline blood flow; flow units = mL/10 g/min; linear units = mm; figures in parentheses were obtained with the radiolabeled microsphere technique.[14]

plying with a conversion factor of 6, based on published experiments[1,2] and unpublished experiments. In our laboratory, 48 pairs of measurements of gastric and duodenal blood flow made simultaneously by the hydrogen gas clearance method and laser Doppler velocimetry were subjected to regression analysis. The correlation coefficient was 0.88 ($r^2 = 0.79$, $p < 0.0001$). In the range of 10–40 mL/100 g/min, the conversion factor was 5.11. This factor was used to convert the instrument readout into mL/100 g/min in the current study. The validity of this technique of measurement has also been extensively documented in the literature.[1-5]

The superior reproducibility of laser Doppler velocimetry over other techniques is in some measure due to averaging measurements over time. Although all other techniques yield "spot" readings and are subject to the spontaneous variation of the circulation, the readout of the laser Doppler flowmeter represents a large number of instantaneous measurements averaged by the computer. In this study a continuous recording of the readout over several minutes was further averaged.

Setting the Staple Closure Height

The thickness of the sigmoid colon was measured at the thickest portion (over the tinea) with a specially calibrated spring-loaded caliper delivering a pressure of 100 g/cm^2. In the dog this value was between 2.8 and 3.7 mm, representing the thickness of two layers of the bowel wall. The staple closure height was set according to this reading, using a stapler (ILS, Ethicon, Somerville, NJ) with provision for such adjustment in the form of a dial, specially calibrated to read up to 3.7 mm. The dialed gap was further checked with a micrometer before use; in all instances the reading was within 10% of the dialed measurement. At the tallest setting (3.7 mm) the closed staples assumed the "O" formation rather than the usual "B" formation.

The Anastomosis Model

Under pentobarbital anesthesia and controlled ventilation, a 2-cm colotomy was made in the sigmoid colon between stay sutures in large mongrel dogs. The mucosal blood flow was determined with the laser Doppler probe at the site selected for stapling or manual suturing, usually 4–5 cm away from the colotomy. The mesenteric arcade at the site of anastomosis was not disturbed. A 25-mm external diameter circular stapler was inserted *via* the colotomy, and after tying a ligature around the shaft, it was closed and fired at a staple closure height determined by bowel wall thickness. After removal of the stapler, the rim of the anastomosis was exposed and blood flow was measured by direct application of the laser Doppler probe to the narrow rim inside of the staple lines. In sutured anastomosis, the bowel was transected with intact mesenteric attachment and without using electrocautery. The blood flow 1 mm from the edge (edge flow) was then measured; the edge flow was found to be identical to the mucosal flow before transection. The least suture tension compatible with a mechanically sound anastomosis was used. After completion of the anastomosis, the flow probe was applied to the mucosal ridge in the space between the suture loops. To verify that the laser Doppler probe was in fact measuring the flow in the rim of the anastomsis, the radiolabeled microspheres technique was used simultaneously to measure sutureline blood flow in one group of dogs (Group I), excising blocks of tissue at the staple line 1 mm thick (measured from the lumen) for counting. The measurements were in accordance (see Table 1).

Experimental Protocol

In Group I, the staple closure height was set equal to the thickness of the bowel walls to be stapled, whereas in Group II, the setting was at half of this value. In Group III, the bowel was first transected without devascularization. Pursestring sutures were inserted at the open ends and stapling was accomplished by the usual technique, taking care to avoid gathering excess tissue by the pursestrings. Group IV was identical to Group I but an additional seromuscular layer of interrupted 5-0 silk was added. In Group V, a single-layered anastomosis was accomplished with interrupted sutures of 5-0 silk, in such a manner as to impede flow the least, in the judgment of the operator. In Group VI, after bowel transection, a double-layered anastomosis was performed using 4-0 chromic catgut for an inner running layer followed by an outer layer of 5-0 interrupted silk sutures.

Human Studies

In patients who had right hemicolectomy, informed consent (approved by the Institution Review Board for the protection of study subjects) was obtained for randomization into stapling and suturing groups. To avoid an "insertion" colotomy, end-to-side ileocolic anastomosis was made, inserting the stapler *via* the transected transverse colon, and the sutureline blood flow (colonic side) was measured *via* the same open end of the colon before closure, using a sterilized probe. The staple closure height was set at 75% of the combined bowel wall thickness to avoid bleeding problems. The average setting was 2.4 mm. The manual anastomosis was done by a conventional two-layered end-to-end technique, with an inner running 4-0 chromic catgut suture and an interrupted outer layer of fine silk, modified so as to allow the sutureline flow to be measured after completion of three fourths of the anastomosis (both layers).

Results

Effect of Stapling on Blood Flow

A stapled anastomosis created with staple closure height equal to the thickness of the two bowel walls is theoretically the least ischemic possible. The blood flow of the narrow rim of mucosa obtained under this circumstance was only 56% of the normal mucosal flow, or a 43% reduction ($p < 0.005$) (Table 1). A 36% reduction was recorded by the radiolabeled microsphere technique used simultaneously. Allowing for the different principles of measurement, the agreement was remarkably close. In three of the five anastomoses, significant bleeding occurred requiring manual tamponade before blood flow could be measured. The staples appeared to be somewhat "loose" and not perfectly aligned as in the stitches of a sewing machine, but no macroscopic leakage was demonstrable. The staples were generally in the "B" configuration, although the legs were separated from the body of staple by a gap of about 1 mm.

Effect of Tight Stapling on Blood Flow

When staple closure height had been set to half of the combined thickness of the bowel walls, the sutureline blood flow was reduced by 69% of mucosal flow ($p < 0.001$, paired t-test). This reduction was greater than that in Group I ($p < 0.01$, unpaired t-test).

In Group III the staple closure height was the same as for Group I, but the bowel was first transected and pursestring sutures were applied to both open ends. The flow reduction at the staple line was 57%, greater than that in Group I ($p < 0.05$, unpaired t-test).

Effect of Manual Suturing on Blood Flow

Double-layered suturing (Group VI) resulted in 59% reduction in blood flow, even when surgical technique of the best tradition was followed. The anastomosis was significantly more ischemic than the stapling in Group I ($p < 0.01$). The least impairment of flow was attained after several attempts with a single-layered manual anastomosis, using fine sutures and meticulous attention to tying tension (Group V, 27% reduction; Group V < Group I, $p < 0.01$, unpaired t-test). Even though no leaks were demonstrable grossly, some of these anastomoses appear mechanically precarious to the surgeon accustomed to more secure suturing.

Addition of a layer of interrupted fine sutures to an appropriately stapled anastomosis (Group IV) exacted a toll on the blood flow, although the difference (Group I *vs.* Group IV, $p > 0.05$) was not significant. The net effect of this anastomosis appeared to be similar to a two-layered manual suturing (55% *vs.* 59% reduction).

Human Data: Stapled Versus *Two-layered Manual Ileocolic Anastomosis*

The mucosal rim (colon side) of stapled end-to-side ileocolostomy was compared with the end-to-end ileocolic manual anastomosis (colonic mucosa) in five patients who had elective right colectomy for carcinoma, with similar extent of resection of the mesentery. There was no dilatation involving the parts anastomosed, and preoperative preparations were the same. Even though the configurations were different, in both groups the mesenteric attachment of the bowel was left intact right up to the anastomotic line. The results in all five patients are listed in Table 2. The three stapled anastomoses had less reduction in blood flow, although the small sample size precluded meaningful statistical analysis. No sutureline bleeding occurred in either group.

Discussion

The two basic considerations in the surgical technique of intestinal anastomosis are mechanical integrity and tissue viability. If the suturing is too loose, the anastomosis is mechanically leaky, and if the suturing is too tight, tissue viability is jeopardized by ischemia. Sound surgical technique must score well on both counts.

The mechanical integrity of stapled anastomosis is well established.[6-8] Stapled anastomoses, as do well-constructed, double-layered, hand-sewn anastomoses,

TABLE 2. *Blood Flow in Ileocolic Anastomoses (Human)*

Patient	Technique	Control MBF	SBF	Percent Reduction
1	Stapled (2.4 mm)	41	17	58
2	Sutured	38	11	71
3	Stapled (2.6 mm)	33	17	48
4	Sutured	48	15	69
5	Stapled (2.3 mm)	34	16	53

MBF = mucosal blood flow; SBF = sutureline blood flow; flow unit = mL/100 g/min.

withstand vigorous challenges such as prostigmine and castor oil administration. Even total obstruction caused by error in stapling may not disrupt the staple line.[8] Bursting strength studies,[9,10] which reflect the degree of healing as well, showed stapling to be superior.

The vascularity of stapled anastomosis is less well studied. Microangiography showed that small vessels do cross the staple lines, through the holes of the B formation of the closed staples.[8,11] There have been no quantitative blood flow studies to date, to the best knowledge of this investigator.

The current study shows that all suturing decreases blood flow, an almost self-evident truism. "Tight" stapling, as contrasted with "loose" stapling, decreases sutureline blood flow. Even though there is no tension data on manual suturing, it is reasonable to infer that tight suturing must have the same effect, a commonly held surgical belief. The "tight" stapling in this experiment may not be too tight by clinical standards, since most staplers have a fixed closure gap at 2 mm, even allowing that the human colon is somewhat thinner than the dog colon. However, some circular staplers currently used allow a minimum gap setting of 1 mm or so, when even lower anastomotic blood flow can be expected. Unduly tight closure of the stapler is instinctively eschewed by the experienced surgeon, but this may still constitute a pitfall to the unwary.

In the most ideal circumstances, when the staple closure height equals the bowel wall thickness, stapling reduced blood flow by 43%, significantly superior to conventional suturing in two layers (59% reduction) or stapling "reinforced" with suturing (55% reduction). However, good vascularity in stapled anastomosis is accompanied by a definite risk of sutureline bleeding, since the stapler makes a circular incision inside of the concentric staplelines, unlike manual suturing. Furthermore, excessively loose staples may be at risk from displacement causing uneven spacing and even leakage. It is likely that in manual suturing, the continuous running layer contributes more to the ischemia. The stapled anastomosis "reinforced" with sutures is in fact a three-layered affair, the resulting decrease in blood flow is not surprising.

The reason for decreased staple line blood supply in the technique using pursestring sutures is not clear. The gathered tissue by the pursestrings added bulk only in the core of the stapler, and the staple lines included only two layers of bowel. Some stretching of the bowel wall at the circumference of the stapler may conceivably have occurred as the "donuts" were being pushed inside the stapler during closure of the machine, thereby interfering with blood flow.

In an attempt to outperform the stapler with manual suturing, this investigator succeeded in the laboratory only after several attempts (and some practice) by using a single layer of fine sutures with meticulous attention to the tying tension, conditions not necessarily always fulfilled in clinical practice. The data support, at least in theory, that single-layered manual anastomosis is the least ischemic, recognizing that in practice it need not be so.

The human data of this study indicate that a somewhat lower sutureline blood flow was accomplished without significant bleeding, by adjusting the staple closure height to 75% of bowel wall thickness. The vascularity of the staple line (about 53% reduction) appeared to be superior to the conventional manual two-layered suturing (about 70% reduction). Such a height also conferred good mechanical security. It is likely that the different anesthetics and suture tensions used by different operators in these cases might account for the greater variance: a large number of cases would be required to discern statistically significant differences.

Although in the acute state, greatly reduced blood flow follows multilayered suturing or tightly stapled anastomosis, it is not known what compensatory mechanisms are triggered and what happens to the decreased blood flow in the hours or days after the operation. Ongoing chronic study in our laboratory shows that severe ischemia may be tolerated in stapled anastomoses without complication in the dog, provided it is not extreme. Other reports have also indicated that the course of focal ischemia (such as ligation of the arcade vessels) in the intestine of the dog is often unpredictable: it may progress to frank gangrene or have no apparent effect.[12,13] Data of ischemia in the dog are thus less likely to be of value as a clinical guide, and more human data are needed to establish a safe lower limit for sutureline blood flow.

The closure height of most circular staplers are nominally fixed, usually at 2 mm. A decade of clinical experience with this type of stapler demonstrated the relative safety of the 2-mm staple closure height for most gastrointestinal stapling. Since the thickness of the gut varies not only with individuals and anatomic regions but also with disease processes, the uniform closure height, although ideal sometimes, must also be relatively ischemic in others. This suggests that even in humans, tolerance of a certain degree of ischemia exists in anastomotic lines. It is important to know, however, in circumstances where blood flow may already be threatened, that attention to staple closure height with respect to bowel wall thickness may help preserve sutureline blood flow.

Inflexibility, a characteristic of all machines, is probably the most notable shortcoming of the stapler. Although staple closure height is adjustable in some instruments, the size and spacing of individual staples are not. A wider choice of diameters of the circular staplers, as well as size and spacing of staples, may enhance its use and reception by the surgical craftsman.

DISCUSSION

DR. GEORGE H. A. CLOWES, JR. (Boston, Massachusetts): Dr. Chung, I would like to ask you a question as to whether we have any correlation between your observations on blood flow and the actual healing of suture lines in the gut of some animals other than the rat. The rat, unfortunately, is a poor animal to choose for something like this. Since rats have great resistance to infection, all you have to do is be socially clean for the rat to heal.

Secondly, most of us were brought up to believe that the serosa and its inflammatory reaction are of greatest importance in localization of leaks and infection at colonic suture lines. Dr. Ravitch's experiments some years ago in which he placed a rubber dam around a suture line and got a large percentage of breakdown showed the importance of the adjacent tissue to walling off infection at the suture lines.

Do I quote you correctly on that? Dr. Ravitch is going to respond.

DR. MARK M. RAVITCH (Pittsburgh, Pennsylvania): I believe one of the problems with almost any study of intestinal anastomosis is that nature is so forgiving and the *vis medicatrix naturae* is so beneficent that unless you do a bad job the bowel will heal very well.

I only need to remind you that we all have learned to apply our sutures lightly and tie them just tightly enough so they do not produce any compression. Yet, Edgar Poth of Galveston has done just the opposite. He puts the sutures through all thicknesses of bowel and says you must tie them tightly until you feel them cut through the muscle. He gets perfect results, and he can show by naked eye observation that whereas in a few minutes the lightly placed suture produces a little area of ischemia when edema comes, in contrast, his tight sutures loosen and there is no ischemia. This seems almost an anti-intellectual, anti-perfection argument, but the fact is that you can go home happy with the technique you have always used even though it disagrees with every one else's technique, and you get good results because nature is so forgiving.

DR. RAPHAEL S. CHUNG (Closing discussion): I thank the discussants for their comments.

Dr. Clowes, the ongoing experiments in our lab in which we tried to produce strictures by tight stapling is still ongoing. All I can say is it is difficult to produce bad results by tight stapling, as Dr. Ravitch has just pointed out.

I would also like to point out the enormous amount of clinical data indicating that over 90% of the time you can get away with closing the staple at a fixed gap of 2 mm, up and down the GI tract.

The significance of these laboratory data is that when the patient is at risk of developing anastomotic dehiscence because of pre-existing adverse conditions such as ischemia, the anastomoses should be sewn or stapled loosely rather than tightly.

Burn Wound Sepsis may be Promoted by a Failure of Local Antibacterial Host Defenses

EDWIN A. DEITCH, M.D.,* R. McINTYRE BRIDGES, M.D.,† MAREK DOBKE, M.D., PH.D.,‡ and JOHN C. McDONALD, M.D.§

From the LSUMC School of Medicine, Shreveport, Louisiana, and the Texas Tech University, Lubbock, Texas

Little attention has been focused on the local burn wound environment, even though burn wound sepsis is a common cause of death in the burn victim. To characterize the effect of the local burn wound environment on neutrophil function and metabolism, the opsonic activity of blister fluid specimens against *Pseudomonas aeruginosa* was measured as was the effect of blister fluid on control neutrophil oxygen consumption using preopsonized zymosan and f-met-leu-phe (FMLP) as stimuli. Blister fluid did not support the killing of *P. aeruginosa* by normal neutrophils as well as normal serum. Additionally, blister fluid inhibited zymosan-stimulated, but not FMLP-stimulated, neutrophil oxygen consumption. The inhibitory effect of blister fluid on zymosan-stimulated oxygen consumption correlated with the extent of complement activation, measured as C3d or C3AI ($p < 0.01$). That blister fluid did not inhibit the FMLP-mediated respiratory burst supports the concept that the blister fluid inhibitory effect on the zymosan-mediated respiratory burst was mediated through the complement receptor. These findings that blister fluid can affect the bactericidal and metabolic activity of normal neutrophils support the concept that cellular function can be altered by the microenvironment in which the cells are bathed. This potential impairment of host defenses within the burn wound could predispose the burn victim to burn wound sepsis.

THE COMBINATION OF the loss of the skin barrier to bacteria and failure of both local and systemic immunity predisposes the burn patient to an increased risk of infection. Despite the fact that the burn wound is the most common portal of entry for invading bacteria, investigation of the effect of the burn wound environment on cellular components of the host's antibacterial defenses has been largely neglected. Previously, we documented that blister fluid will not support the phagocytosis or intracellular killing of *Pseudomonas aeruginosa* by control neutrophils collected from healthy volunteers as well as normal serum.[1,2] Furthermore, we found that the biologic effect of burn wound blister fluid was not limited to neutrophil bactericidal activity, but that blister fluid will also inhibit the blastogenic response of normal lymphocytes to the mitogen phytohemagglutinin (PHA).[3,4]

Although the exact mechanisms by which the blister fluid specimens affected neutrophil and lymphocyte function could not be fully determined from these previous studies, both the blister fluid opsinopathy and the lymphocyte inhibitory activity was associated with local consumption of C3 and the generation of complement breakdown products.[2,4] Since neutrophils have surface membrane complement receptors and evidence exists that C3 breakdown products can modulate neutrophil function through these receptors,[5-7] the current study was performed to correlate the levels of C3 and its stable metabolic breakdown product C3d, with the biologic effect of blister fluid on control neutrophil bactericidal and metabolic activity. The results of this study indicate that burn blister fluid has impaired opsonic activity for *P. aeruginosa,* and will depress the metabolic response of control neutrophils to zymosan. Furthermore, the suppressive effect of the blister fluid specimens on neutrophil metabolism correlated directly with the magnitude of complement activation. Further support for the role of complement breakdown products as mediators of impaired neutrophil function came from experiments documenting that blister fluid impaired complement-

mediated, but not complement-independent, metabolic responses. Thus, the results of this study support the concept that a local failure of neutrophil function could occur in the burn wound and be mediated by local activation of humoral factors, such as complement. Thus, our results clearly show that local immunity is impaired after thermal injury, and that this impairment is due to more than just local destruction of the skin barrier. The failure of local immune defenses could predispose the burn victim to burn wound sepsis by allowing bacteria to colonize more easily and invade the burn eschar.

Patients, Materials, and Methods

Twenty-four patients admitted to the Louisiana State University (LSU) Burn Center in Shreveport form the basis for this study. The mean ± SD burn size was 35 ± 19% TBSA. The mean ± SD age was 31 ± 17 years, with 17 male and seven female patients. All patients were admitted directly to the Burn Unit within 6–12 hours of their injury. Resuscitation was based on the Parkland formula and was modified according to the clinical response of each patient. The burn wound area from which the blister fluid was obtained was not treated with topical antimicrobial agents. No prophylactic antibiotics were administered and none of the patients had sepsis at the time of the study.

Blister Fluid

Blister fluid was obtained by needle aspiration within 12–18 hours of thermal injury before the formation of any gel-like coagulation. Sterility was verified by culturing the blister fluid on blood agar plates for 24 hours. Each specimen was divided into aliquots and stored at −70 C until used.

Cell Preparation

A 15-mL sample of heparinized blood (10 U/mL) collected from healthy volunteers was mixed with 6% dextran and gravity sedimented at room temperature for 60–120 minutes. The leukocyte-rich supernatant was aspirated and washed three times in minimal essential medium, and viability was established by trypan blue exclusion.

Bacteria

P. aeruginosa strain 12-4-4 was obtained from Brooke Army Hospital, Fort Sam Houston, Texas. Bacteria were grown in tryptic soy broth for 18 hours at 37 C and then washed twice in phosphate-buffered saline (pH 7.2). The initial bacterial count was determined spectrophotometrically (620) and verified by pour plate assay.

Bactericidal Assay

The bacterial assay has been previously described.[2] Briefly, leukocytes at a final concentration of 5×10^6/mL were incubated with 10^6 CFU *P. aeruginosa* in minimal essential medium supplemented with either control serum or blister fluid (10% or 30%, v/v). The leukocyte–bacterial suspension was incubated at 37 C on a rotating shaker. Aliquotes of the suspension were pour plate assayed after 30 and 90 minutes of incubation to determine the total number of viable bacteria.

C3 Determination

Native C3 concentrations were measured by rocket immunoelectrophoresis in 1% agarose gel containing 0.01 M edetic acid and 0.8% (v/v) antiserum against native C3. Antiserum against native C3 was prepared from goat anti-human C3 (betalc/betala globulin) serum as described elsewhere.[8]

C3d Determination

Serum C3d levels were measured by rocket immunoelectrophoresis using a rabbit anti-human C3d serum. In this method, native C3 from edetic acid–plasma was precipated with 22% polyetheylene glycol (molecular weight 8000) and C3d was assayed in the supernatant. Medium electroendosmosis 1% agarose with 1.25% anti-C3d serum was used for immunoelectrophoresis procedures.[9]

C3 Activation Index

The C3 activation index (C3AI) expressing the C3d to native C3 ratio was computed as follows[10]:

$$\mathrm{C3AI} = \frac{\mathrm{C3d\ (mg/dL)} \times 100}{\mathrm{C3\ (mg/dL)}}$$

Hemolytic Complement Assay

Total hemolytic complement activity (CH100) was determined by the quantiplate technique.[2] In this system, the test serum is placed into wells cut in agarose plates containing standardized sheep erythrocytes sensitized with hemolysin. The degree of hemolysis is then determined by measuring the area of hemolysis surrounding the well.

Oxygen Consumption of Peripheral Blood Neutrophils

The assay of neutrophil oxygen consumption was performed polarographically using a Clark's electrode as described by Nakamura et al.[11] A suspension of 10^6 control neutrophils was placed in a Clark electrode chamber containing control medium, normal serum (20% or 80% v/v), or blister fluid (20% or 80% v/v). Five

TABLE 1. *Comparison of the Effect of Control Medium, Normal Serum, and Blister Fluid on Control Neutrophil Oxygen Consumption*

		Oxygen Consumption (nmol/O_2/min/10^6 cells)			
	N	Resting	Zymosan Stimulated	Total	SI
Media	10	0.15 ± 0.03 (a)*	0.51 ± 0.10 (a)	0.66 ± 0.12 (a, b)	4.6 ± 0.45 (a)
Blister fluid	24	0.22 ± 0.06 (b)	0.42 ± 0.14 (b)	0.64 ± 0.16 (a)	3.1 ± 0.89 (b)
Normal serum	9	0.18 ± 0.02 (c)	0.63 ± 0.22 (a)	0.81 ± 0.21 (b)	4.7 ± 1.34 (a)

* Groups that are statistically similar have the same letters in parentheses, whereas groups that are statistically different ($p < 0.05$) have different letters in parentheses. All values are expressed as mean ± SD. Blister fluid and normal serum specimens tested at 80% v/v. SI = stimulation index, which is computed by dividing total oxygen consumption by resting oxygen consumption.

microliters of 50 mM NaCN was added to inhibit cytochrome oxidase-dependent mitochondrial respiration. Baseline resting (unstimulated) neutrophil oxygen consumption was measured after a 6-minute adjustment period for temperature equilibrium. One minute later, zymosan preopsonized with normal serum (60 mg/mL) was added to the neutrophil suspension and the zymosan-stimulated increase (respiratory burst) in oxygen consumption was measured. Preopsonized zymosan was chosen as a probe to evaluate the complement-mediated oxidative response, since its phagocytosis is mediated through the C3b receptor. Since the synthetic peptide formly-met-leu-phe (FMLP) stimulates oxygen consumption through the FMLP receptor, which is independent of the complement receptor, it was chosen as a probe to evaluate the effect of blister fluid on the non-complement-mediated respiratory burst. FMLP was tested at a concentration of 10^{-7} molar.

Total oxygen consumption was computed by combining the values of the resting and stimulated oxygen consumption. The stimulation index (SI) was computed by dividing the stimulated oxygen consumption by the resting oxygen consumption.

Statistics

Results were expressed as mean ± SD or SEM. The statistical analyses were performed on an Apple II computer using the Stat pack program (Human Systems Dynamics, Northride, CA). Comparisons between groups were performed by Student's t-test for paired or unpaired data as appropriate. Correlations were analyzed by linear regression analysis. Values of $p < 0.05$ were considered statistically significant.

t-test		$p < 0.001$	$p < 0.001$	$p < 0.001$	$p = 0.24$

* Results are expressed as mean ± SEM.

Results

When control neutrophils from healthy volunteers were incubated in blister fluid, several phenomena were observed. The level of resting (unstimulated) oxygen consumption of these cells suspended in blister fluid was increased compared with neutrophils suspended in media, whereas the zymosan-stimulated burst of oxygen consumption was lower in neutrophils suspended in blister fluid than those suspended in medium (Table 1). Since some of the changes between the neutrophils suspended in medium *versus* blister fluid could have been due to there being no protein source in the medium, the cells were also tested after suspension in pooled normal serum (80% v/v). Neutrophils suspended in normal serum had higher resting levels of oxygen consumption than cells suspended in medium ($p < 0.02$), but lower levels than those suspended in blister fluid. However, zymosan-stimulated oxygen consumption was higher in the neutrophils suspended in normal serum than neutrophils suspended in medium ($p = 0.14$) or blister fluid ($p < 0.05$) (Table 1). These results indicated that blister fluid effected both unstimulated and zymosan-stimulated oxygen consumption differently than medium or normal serum.

Next, we measured the complement levels (C3 and C3d) and hemolytic activity of these blister fluid specimens (CH100). As seen in Table 2, the levels of C3 were lower in the blister fluid specimens than in normal serum ($p < 0.01$). Additionally, the complement present in the blister fluid appeared to have been activated, since the level of C3d, the activation product of C3, was increased ($p < 0.01$), as was the C3 activation index (C3AI) ($p < 0.01$) (Table 2). Neither C3, C3d, C3AI, nor CH100 ($p > 0.24$) levels in the blister fluid correlated with the increase in resting neutrophil oxygen consumption. However, there was a correlation between C3 activation and depression of zymosan-stimulated oxygen consumption by the neutrophils, whether measured as C3AI ($R = -0.52$, $p < 0.01$), or C3d ($R = -0.57$, $p < 0.01$) (Fig. 1). Since there was no correlation between zymosan-stimulated oxygen consumption and the level of C3 ($p = 0.64$) or hemolytic activity ($p = 0.62$) of the blister fluid specimens, it appears that the decrease in zymosan-stimulated oxygen consumption of neutrophils suspended in blister fluid is associated more with complement activation than with the absolute levels of C3.

Previously, we documented that neutrophils suspended in blister fluid at 10% v/v do not ingest and kill *P. aeruginosa* as well as neutrophils suspended in normal serum. This defect in blister fluid biologic activity was primarily due to a deficiency of opsonic activity in the blister fluid, although the blister fluid impaired intracellular killing of phagocytized pseudomonads.[1] Since the concentration of blister fluid used in the bactericidal and metabolic assays were different and blister fluid concentration may be of biologic importance, we measured the effects of different blister fluid concentrations on bacterial killing and zymosan-stimulated oxygen consumption. Blister fluid at 10% or 30% v/v did not impair zymosan-stimulated oxygen consumption of control neutrophils compared with the same cells suspended in medium ($p < 0.14$), although these blister fluids at 80% v/v inhibited the zymosan-stimulated burst of oxygen consumption (Fig. 2). In contrast to the oxygen consumption assay, increasing the concentration of blister fluid from 10% v/v to 30% v/v or 80% v/v (data not shown) in the bactericidal assay restored neutrophil function to normal (Fig. 3). These results highlight the complexity of the relationship between complement and neutrophil function and illustrate that the same stimulus may influence various neutrophil functions differently.

To determine whether the inhibitory effect of blister fluid on the respiratory burst was limited to complement-mediated stimuli or effected both complement and noncomplement-mediated stimulated oxygen consumption, the effect of blister fluid on FMLP stimulation of neutrophils was measured. The levels of FMLP (10^{-7} molar) stimulated oxygen consumption of control neutrophils suspended in blister fluid was not different from neutrophils suspended in medium or serum (Fig. 4). These results indicate that the inhibitory effect of blister fluid on stimulated oxygen consumption may be mediated, at least in part, through the complement receptor.

Discussion

Burn wound sepsis occurs when bacteria colonizing the burn eschar successfully invade the viable subeschar tissue. In this situation, the humoral and cellular elements of the inflammatory response become a major host defense barrier.[12] That burn wound sepsis remains a frequent cause of morbidity and mortality in patients with major burns, despite the development of topical antimicrobial drugs, emphasizes that the patient's local antibacterial defenses have failed. Whether the failure of local immunity is due to the presence of burn-induced

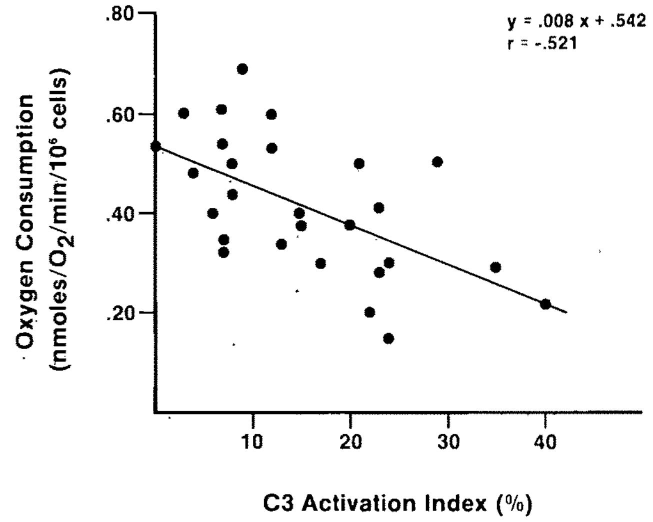

FIG. 1. There was a relationship between oxygen consumption (nmol/ O_2 min/10^6 cells) and complement activation measured as the C3 activation index ($R = -0.521$, $p < 0.01$).

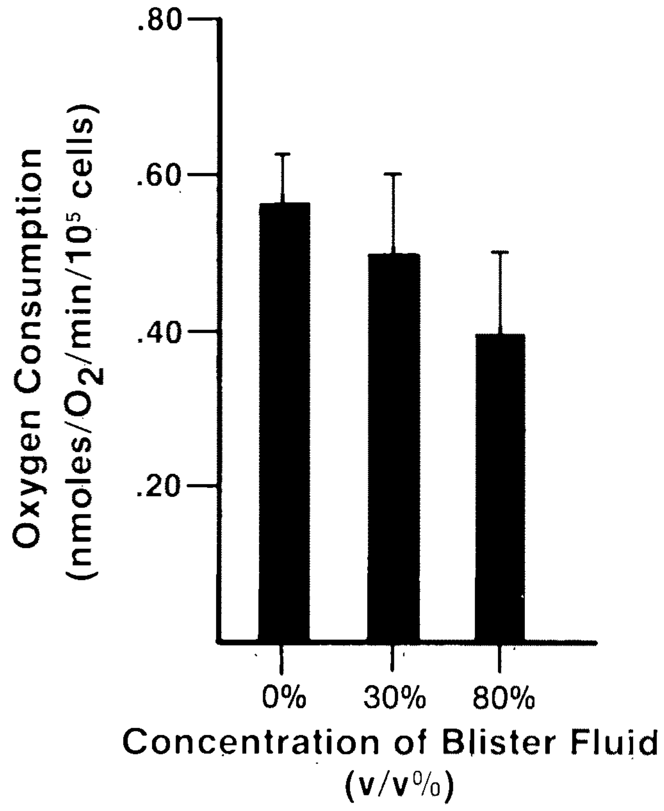

FIG. 2. The concentration (v/v%) of blister fluid ($N = 6$) in the oxygen consumption assay effected the amount of oxygen consumed by normal neutrophils stimulated by opsonized zymosan, since oxygen consumption in the presence of blister fluid at 80% v/v (respiratory burst) was lower than when the neutrophils were incubated at 10% or 30% v/v concentrations of blister fluid ($p < 0.03$).

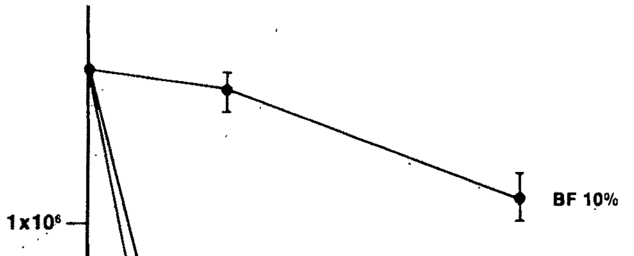

FIG. 3. Rate (mean ± SEM) of killing of *P. aeruginosa* by normal neutrophils incubated with blister fluid (N = 8) at 10% or 30% v/v concentration, or normal serum (N = 3) at 10% or 30% v/v.

suppressive factors, a local deficiency of normal host defense factors, or a combination of these or other factors, has not been extensively studied. For this reason, we have been interested in examining the effect of burn wound blister fluid on normal neutrophil and lymphocyte function and correlating its biologic activity with its chemical composition. In this way, it may be possible to understand how the local burn wound microenvironment may modulate the cellular arm of the host's antibacterial defense system. In previous work we documented that blister fluid will not support the opsoninophagocytosis or intracellular killing of *P. aeruginosa* by control neutrophils, although *Staphylococcus aureus* are killed normally,[1] and that a subset of the blister fluid samples inhibits mitogen-stimulated lymphocyte blastogenesis.[3] Further study of these blister fluid specimens suggested that the failure of the blister fluid to support the ingestion of pseudomonads by normal neutrophils was due to the local activation and consumption of complement in the burn wound and was not primarily due to the presence of inhibitory factors.[2] In contrast, blister fluid directly suppressed the response of normal lymphocytes to the mitogen PHA and the lymphocyte suppressive factor(s) appeared to be related to C3 metabolic products.[4] Thus, although the biologic activity of blister fluid appears to be different for different cell populations, in both instances the cellular changes were associated with complement activation.

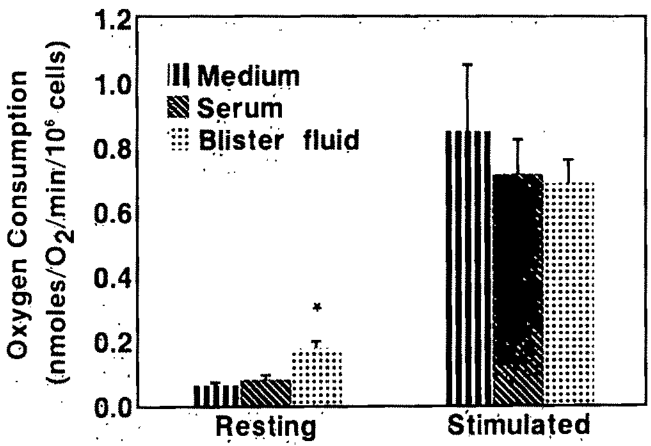

FIG. 4. No difference was found between the effect of control medium, normal serum (80% v/v), and blister fluid (80% v/v) on the FMLP-mediated (10^{-7} M) respiratory burst.

The current studies were performed to further characterize the biologic effect of blister fluid on normal neutrophil bactericidal activity and metabolism. Since bacterial phagocytosis and killing are accompanied by a dramatic rise in nonmitochondrial respiration, which correlates with the zymosan-stimulated oxygen (respiratory) burst,[13] and blister fluid did not support the ingestion and killing of *P. aeruginosa,* we were especially interested in measuring the effect of blister fluid on control neutrophil oxygen consumption. We found that blister fluid directly inhibited the respiratory burst of zymosan-stimulated neutrophils, and the degree of inhibition of the neutrophil's metabolic response to zymosan correlated with the degree of complement activation, measured as the level of the C3 metabolic product C3d ($p < 0.01$). The blister fluid effect on neutrophil bactericidal activity was maximal at 10% v/v, whereas its effect on oxygen consumption was maximal at 80% v/v concentration. The blister fluid-mediated effect on the respiratory burst appeared to be specific to complement-mediated stimuli, since blister fluid did not reduce the respiratory burst of neutrophils exposed to FMLP, which is a noncomplement-mediated stimulus. Thus, the blister fluid specimens appear to have disparate effects on neutrophil bactericidal activity and neutrophil metabolism, which is concentration and stimulus dependent.

There are several theoretical explanations for these findings. It is known that neutrophil receptors modulate the cell's ability to respond to stimuli by changing the affinity of the receptor according to the cell's environment.[14] For example, from studies using the chemoattractant FMLP, it is clear that as the concentration of FMLP increased, the neutrophils adapt by decreasing receptor affinity for this chemoattractant. This results in the neutrophil becoming chemotactically paralyzed (deactivated) when exposed to a high concentration of a chemoattractant,[15] while at the same time, neutrophil degranulation is increased. Thus, chemoattractants, such as C5a and FMLP, at concentrations that cause chemotactic deactivation, also promote neutrophil degranulation. In essence, these changes in receptor affinity potentially allow the cell to adapt its response according to its microenvironment. Since the respiratory burst is associated with a low receptor affinity state,[14,16] the changes we observed with zymosan could be due to alterations in complement receptor affinity induced by the blister fluid. That is, the blister fluid at an 80% v/v concentration could stimulate the basal neutrophil metabolic rate, while simultaneously decreasing the affinity of the cell for subsequent complement-mediated stimuli. Thus, when zymosan is added, the cells would be relatively refractory to this second complement-mediated stimulus. The scenario of increased basal oxygen consumption and decreased stimulated oxygen consumption of neutrophils suspended in blister fluid could, therefore, be related to neutrophil deactivation or receptor-mediated down regulation. This same pattern of increased basal and decreased stimulated oxygen consumption could result from a blister fluid-mediated increase in basal energy utilization resulting in decreased energy stores (metabolic exhaustion). This possibility is unlikely since the cells responded normally to FMLP.

Another possible explanation for the different effects of blister fluid on bactericidal activity *versus* zymosan-mediated oxygen consumption is that the blister fluid in some fashion dissociates oxygen consumption from bactericidal activity.[17] This dissociation could be related to the uncoupling of oxygen consumption from glucose utilization resulting from different sensitivities of these pathways to modulation by factors present in the blister fluid or because the neutrophil uses nonoxygen-dependent pathways for microbicidal activity.[18] Lastly, the blister fluid may contain other selective inhibitors of oxygen consumption that only become apparent when zymosan is used as a probe and the blister fluid is present at high enough concentrations. It is likely that our findings are not the result of a single mechanism, but may be the summation of several of the above described mechanisms.

Since both the phagocytosis of *P. aeruginosa* and the zymosan-mediated respiratory burst are complement-mediated phenomenon and evidence has accumulated that various fragments of C3 can modulate neutrophil, macrophage, and lymphocyte function,[5-7,19] we measured native C3, C3d, and C3AI concentrations in the blister fluid specimens. The levels of C3 were lower, whereas the levels of the C3 metabolic product C3d and the C3AI were higher in the blister fluid specimens than in control serum, indicating that native C3 in blister fluid has been activated (Table 2). No relationship between absolute complement levels (C3 and C3d) or complement activity (C3AI or CH100) and basal oxygen consumption was found, indicating that the blister fluid-mediated increase in basal neutrophil oxygen consumption is not associated with increased C3 activation. However, there was an inverse correlation between C3 activation, whether measured as C3d or C3AI, and zymosan-stimulated oxygen consumption (Fig. 1). The nature of the specific complement activation product that modulates the impaired respiratory burst of control neutrophils to zymosan is not known, but based on the work of Ogle et al. it may be fluid phase C3b.[5]

Although the association between complement activation and inhibition of the zymosan-stimulated respiratory burst is statistically significant, the degree of correlation ($R = 0.52$) does not account for the entire inhibitory effect of the blister fluid on the respiratory burst. Therefore, other factor(s), such as the prostaglandins, serotonin, histamine, or interleukin-1,[20] all of which have been found in blister fluid, may also modulate the zymosan-mediated respiratory burst.

The relationship between the complement system and neutrophil bactericidal and metabolic responses are of great potential clinical importance, since *in vivo* bacterial phagocytosis and killing by phagocytes is mediated to a large extent by the C3 receptor.[21] Our findings that blister fluid can affect the bactericidal and metabolic activity of normal neutrophils emphasizes that cellular function can be altered by the microenvironment in which the cells are bathed. The findings that blister fluid impairs normal neutrophil bactericidal activity and metabolism is consistant with the work of Alexander and associates, who have shown that a consumptive opsinopathy occurs in the serum of burn patients.[22] Furthermore, Cohen et al.[23] and Polk et al.[24] have documented an opsonic failure of diluted serum in trauma victims and stressed or debilitated patients, whereas Lanser et al. have found that the serum of trauma victims contain an inhibitor of neutrophil metabolism.[25] Thus, our findings that burn wound blister fluid can impair neutrophil function correlates well with the systemic effects documented by other investigators in the serum of victims of thermal or mechanical trauma. Based on the results of these experiments and our previous work, we believe that blister fluid by altering normal neutrophil function could promote the uncontrolled local growth of microorganisms in the burn wound. Furthermore, failure of local defenses could be the first step in the development of burn wound sepsis. However, the ultimate clinical result of the failure of local antibacterial defenses would depend on additional factors, including the patient's overall immune state.

DISCUSSION

DR. P. WILLIAM CURRERI (Mobile, Alabama): Dr. Deitch and his colleagues have previously reported investigations that have suggested that there are local factors in blister fluid which have profound effects on phagocytosis and intracellular killing by control neutrophils collected from healthy volunteers.

In this presentation they examine opsonic activity and cellular metabolism as reflected by oxygen consumption to test for a relationship between complement activation and neutrophil oxygen consumption, the latter of which is a known important process required for intracellular killing of bacteria.

Their data indicate that there is a severe decrease in zymosan-stimulated oxygen consumption by neutrophils incubated in blister fluid compared with such cells incubated in media or normal serum. Furthermore, the blister fluid appeared to have been activated since there was a significant increase in C3d and the activation index.

At best a modest negative correlation was demonstrated between C3 activation and the depression of zymosan-stimulated oxygen consumption by the neutrophils.

The authors have suggested several theoretical explanations for these findings including down regulation of the neutrophil as a result of exposure to high levels of activated complement, the disassociation of oxygen consumption from bacteriocidal activity, and the presence of other selective inhibitors of oxygen consumption that only become apparent in the presence of blister fluid when zymosan stimulation is used as a metabolic probe.

Because of the relatively low correlation between complement activation and oxygen consumption observed in these studies (as illustrated by an R value of only 0.5–0.6), the latter two explanations become more attractive.

The data presented today did not strongly suggest a cause and effect between complement activation and the subsequently observed decreased stimulated oxygen burst as a single mechanism associated with decreased neutrophil inhibitory function. Nevertheless, these observations are intriguing and will certainly stimulate these and other investigators to search for other selective inhibitors of oxygen consumption within burn blister fluid and to further delineate the role of activation of complement as a direct cause of neutrophil down regulation.

I would like to direct a number of specific questions to the authors.

First, do the authors believe that their observations can be extended to third degree burn where blister formation is not prominent? Such burns are relatively dry, and therefore, might present a different local wound environment.

Secondly, staphylococcal bacterial infection of the second degree burn wound occurs at least as commonly as Pseudomonas infection of the second degree burn wound. If the proposed mechanism of down regulation of neutrophil activity is an important component in local immunity, how do the authors explain the common finding of staphylococcal colonization of second degree burns? Finally, have the authors tested the effect of blister fluid on neutrophils collected from burn patients? Such studies might elucidate the presence of systemic circulating factors that serve to block complement receptors on the neutrophil, which are independent of the local environment created by the blister fluid.

DR. JOHN A. MANNICK (Boston, Massachusetts): As usual I am impressed by the originality of Dr. Deitch's research, and I am convinced of the accuracy of his data.

I am slightly less convinced by his conclusions. I believe that it is apparent that something in blister fluid is inhibiting neutrophil activation, at least by zymosan. Is it possible that what is happening here has nothing to do with complement? For example, can we attribute all of this to an increase in proteolytic enzymes in the blister fluid? Certainly most inflammatory exudates including peritoneal fluid have enough proteolytic enzymes to digest off complement receptors from neutrophils. Could this be what is happening?

I believe this sort of question could be answered if Dr. Deitch has any data about the expression of complement receptors on the neutrophils in his experiments. Since technology is currently available to allow these experiments to be done, that would be one way of settling the issue.

I am more disturbed by the question of whether or not the blister fluid and its effects on neutrophil activation actually has anything to do with the invasion of the burn wound by bacteria. I would have believed that perhaps a more important gauge of the host defense against bacteria would be the function of the neutrophils in the capillaries at the edge of the burn wound. Dr. Francis Moore, Jr. at our hospital has shown convincingly that the circulating neutrophils in patients with burns of equivalent size to those studied by Dr. Deitch are very activated as they circulate *in vivo* as reflected by severely increased representation of complement receptors on the cell surface, and we have been unable to show that these cells lack ability to kill bacteria when studied *in vitro*. Therefore, I believe that Dr. Deitch has presented us with some interesting experimental findings, but I am not sure whether or not they have relevance to the invasion of the burn wound by pathogenic bacteria.

DR. BASIL A. PRUITT, JR. (Fort Sam Houston, Texas): I, too, would like to compliment Dr. Deitch and his coauthors on another in their interesting series of studies dissecting the factors responsible for the increased susceptibility to infection after injury, and to thank him for providing me with the manuscript well in advance of the meeting.

I would like to preface my further comments with a semantic niggle. That is, burn wound sepsis refers to the clinical constellation of organ failure that is elicited by hematogenous dissemination of microorganisms or their metabolic products from a site of invasive burn wound infection. Surely Dr. Deitch means burn wound invasion rather than burn wound sepsis.

The data presented suggest that burn wound blister fluid impairs complement-mediated phagocytosis, and inhibits complement-mediated neutrophil oxygen production but does not affect complement-independent oxygen production by neutrophils stimulated by FMLP. These findings are interpreted as indicating that blister fluid impairs neutrophil function in the wound, and thereby permits local microbial growth. Since blisters are characteristic of second degree burns, one might conclude that such wounds are particularly susceptible to infection, but clinically they are much more resistant to infection than third degree burns where there are no blisters, and I would like the authors to explain that paradox.

To assist us in evaluating his findings, Dr. Deitch will need to supply us with a few more experimental details. First, were differential counts performed on the neutrophil preparations to ensure a comparable cell population in each test system? Second, since oxygen production of normal neutrophils should increase 10–20-fold when stimulated, how do you explain the modest threefold increase you observed? Third, how confident are you that variable aggregation and adherence of polymorphonuclear leukocytes to the electrode membrane did not affect your measurements? Fourth, since endotoxin can influence PMN function, did you measure endotoxin levels in the blister fluid samples to assess whether they were responsible for the observed changes?

I also ask what you consider the clinical implication of these data to be? Since many bacteria have amino acid sequences analogous to FMLP and responsiveness to that material was maintained, was polymorphonuclear chemotaxis in the wound actually decreased? Lastly, I ask whether this study leads you to recommend the immediate debridement of all bullae and blisters from second degree burn wounds?

DR. ANDREW M. MUNSTER (Baltimore, Maryland): I thank Dr. Deitch for not providing me with a copy of the manuscript because it makes you think on your feet quickly.

I have a few minor questions. There is another receptor on the neutrophil, and that is the FC receptor, and I am not altogether convinced from his data that he is showing active inhibition of function rather than deficiency disease. Therefore my question is: did he measure IgG levels and IgM levels, particularly IgG levels in the blister fluid?

This is particularly important because a number of groups currently are looking at the effect of the intravenous IgG preparations on protection from burn wound sepsis.

My second question is: where did the Pseudomonas come from that these neutrophils were tested against because we have recent evidence in our laboratory that shelf Pseudomonas is not handled the same way by neutrophils as a clinical isolate from the same patient. Finally, I would like to echo the other comments inasmuch as I do not known what blister fluid is. I do not know if it can be representative of local wound environment or not, particularly in light of previous work from Galveston, performed 15 years ago, which show that the movement of the various components of IgG and IgM differ in the burn area inwards, outwards, and into the cell. Therefore, what do you think the blister fluid means?

DR. J. WESLEY ALEXANDER (Cincinnati, Ohio): I also compliment Dr. Deitch on his clear presentation and continued contributions to this particular area and emphasize that he is trying to look at the potential mechanisms of altered host resistance caused by blister fluid as it leaks out into the wound.

(Slide) There is great interest regarding complement activation in surgical diseases, and I want to point out that most of the conditions that are associated with intense and chronic complement activation are associated with an increase in the incidence of bacterial infections.

There has been particular interest in the breakdown products of C3 in this phenomenon. As you will recall, C3 is cleaved into C3a and C3b. C3b is the larger fragment of these, and it usually attaches very soon to a susceptible membrane if it is to participate in phagocytosis.

If it does not set down on that membrane within a few seconds, it undergoes a confirmational change in its protein structure and is unable to attach to those membranes and is called fluid phase C3b.

Fluid phase C3b is broken down to C3bi and further to C3c and C3d. Dr. Deitch used one of these in his investigations.

C3b is a particularly interesting fragment because it can induce phagocytosis when bound, but it inhibits phagocytosis and the killing of bacteria when it is in the fluid phase. Additionally, it can directly interact with the membranes of phagocytic cells to stimulate production of active oxygen species and to induce the release of a variety of enzymes and degranulation from the neutrophils.

When injected intradermally with bacteria into the backs of guinea pigs, it can increase lesion size, using the Burke model, indicating that there is an increase in the infectability, and when injected intraperitoneally with bacteria it can inhibit the clearance of bacteria from the peritoneal cavity.

Therefore, C3b may have an important effect by interfering with phagocytic function not only by depletion of the active C3b that sits down on the membrane and increases phagocytosis, but also by serving as an inhibitor substance, which inhibits the subsequent function of neutrophils.

I must say that we have a different outbred population in Cincinnati than Dr. Mannick does in Boston. We do see neutrophil defects in burned patients as a variety of other subjects.

I ask Dr. Deitch several questions related to this. One, have you fractionated the blister fluid to try to identify specific inhibitors related to the complement system? Second, have you dialyzed blister fluid to look for inhibitors because there are those related to the leukotrienes in prostaglandins, which also have an inhibitory effect on neutrophil function? Finally, have you looked for any suppressive peptides such as those that have been described by Dr. Mannick and Dr. Ozkin?

Dr. Stanley M. Levenson (Bronx, New York): I would like to ask Dr. Deitch one question. As I understand it you interpret the relative differences in the C3 and C3D levels in the burn blister fluid compared with those in the serum as reflecting activation of complement in the burned tissue and/or in the blister fluid itself. Would an alternate interpretation be that the differences reflect differences in the rates at which these molecules cross the heat-damaged capillary walls because of the differences in their molecular weights?

Dr. George H. A. Clowes, Jr. (Boston, Massachusetts): I would like to add one question. We have recently studied in some detail the presence of interleukin I and its products, and we know that this stimulates the growth of granulation tissue and other defensive functions, and also can be an inhibitor.

It seems to me that you have heard several discussants, all of whom have suggested different things in the fluid. It is going to be your problem to sort it out now.

Dr. Edwin A. Deitch (Closing discussion): I thank all the discussants for their questions. I believe the best way of approaching these questions may be by summarizing some of the questions so that I have adequate time to address them all.

First, let me describe what blister fluid is and answer some of the questions about what could be in it.

We have published previously some work on cross-electrophoresis measuring 21 proteins in blister fluid as well as similar levels in serum immediately after injury. What we found was that the blister fluid was a filtrate of the plasma, and as Dr. Levenson suggested, whatever proteins are in the plasma come across into the blister fluid. With the exception of the C3 breakdown products, the concentration of proteins in blister fluid reflects their concentration in serum. The level of C3d in the blister fluid is about five times the level in the plasma; therefore, it appears as if proteins are going across and there is a linear relation between the log molecular weight of the protein and its concentration in blister fluid with the exception of C3 breakdown products.

My best explanation for these findings is that C3d is being produced locally due to activation of complement in the burn wound.

The question about interleukin I is very interesting. Last year I did some work in collaboration with Dr. Tom Kupffer and Dr. Chip Baker from Yale, and we presented data showing that blister fluid has high levels of interleukin I-like activity, which may be due to epidermal thymocyte activating factor (ETAF). In fact, the levels of IL-1 activity in blister fluid were approximately 100 U/mL when it was quantitated. Therefore, the blister fluid does contain high levels of interleukin I activity and thus could be at least a source for these factors that circulate throughout the body.

I believe Dr. Alexander has said it very well. That is, what I am trying to do with these experiments is to determine what is happening at the level of the local wound. We all know that bacteria have to cross mechanical barriers to gain access to the body. Whenever that barrier is weakened, whether by the presence of a Foley catheter in the bladder, an endotracheal tube in the lung, an IV in a vein, or damaged skin, the net result is that bacteria may cross more easily.

The first defense that is called into play once bacteria have crossed these mechanical barriers and invaded viable tissue is the inflammatory response. Humoral factors that are associated with the inflammatory response cooperate with locally recruited neutrophils to increase bactericidal capabilities of these phagocytic cells.

What we are looking at with blister fluid is: does the humoral factors that are present in the burn wound affect the biological activity of normal neutrophils? What we have found is that blister fluid effects neutrophil function differently than normal serum or neutral media.

As far as how blister fluid is mediating the changes in neutrophil function, I do not believe that we can say with certainty that all of the affects of blister fluid on neutrophil function is being mediated through complement factors. However, there is a statistically significant inverse correlation between the level of complement activation, measured as C3d or the C3AI and neutrophil metabolism.

As Dr. Alexander mentioned, we also have found early on after a burn injury that neutrophil function is impaired, especially chemotaxis. Therefore, I believe that local immunity must be severely impaired, since the neutrophils reaching the burn wound may not be normal and the humoral microenvironment in which the PMMs must function is not optimal.

I would like to address next what I believe is one of the most difficult questions to answer. That is, do our results with second degree burns apply to third degree burns. This is a difficult question to answer with certainty, but I believe the answer is yes. Drs. Baxter and Dobke have collected wound fluid from patients with third degree burns and have found that this fluid is biologically similar to blister fluid.

I believe the study of blister fluid is cleaner than wound fluid, since blister fluid is sterile and does not contain cellular debris. We have tested for endotoxin, and blister fluid is negative. Also, I believe that any biological fluid that reaches the burn wound will be activated, since this fluid will be exposed to denatured collagen and damaged tissue. In this regard, there is no difference between second and third degree burns, since in both instances collagen is exposed, and exposed collagen can activate both the coagulation cascade and the complement system.

To answer some technical questions, I can answer that we checked the neutrophils' viability. We also checked them to make sure that they were highly pure. Dr. Pruitt accused us of having puny neutrophils. Based on our previous work, as well as the work of others, the stimulation index that we find with our neutrophils is similar to what is reported around the country. The stimulation index, depending on the stimulant, zymosan or FMLP, is generally between 3 and 5.

Thank you for your attention.

PIPRACIL®
STERILE PIPERACILLIN SODIUM FOR INTRAVENOUS AND INTRAMUSCULAR USE

A Brief Summary
Consult package insert for full prescribing information.

INDICATIONS AND USAGE: Therapeutic. PIPRACIL is indicated for the treatment of the following serious infections caused by susceptible strains of the designated organisms: Intra-abdominal, urinary tract, gynecologic, lower respiratory tract, skin and skin structure, bone and joint, gonococcal infections, and septicemia.

Prophylaxis. PIPRACIL is also indicated for prophylactic use in surgery including intra-abdominal (gastrointestinal and biliary) procedures, vaginal hysterectomy, and cesarean section.

CONTRAINDICATIONS: A history of allergic reactions to any of the penicillins and/or cephalosporins.

WARNINGS: Serious and occasionally fatal hypersensitivity (anaphylactic) reactions have been reported in patients receiving therapy with penicillins. These reactions are more apt to occur in persons with a history of sensitivity to multiple allergens.

There have been reports of patients with a history of penicillin hypersensitivity who have experienced severe hypersensitivity reactions when treated with a cephalosporin. Before initiating therapy with PIPRACIL® sterile piperacillin sodium, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, and other allergens. If an allergic reaction occurs during therapy with PIPRACIL, the antibiotic should be discontinued. The usual agents (antihistamines, pressor amines, and corticosteroids) should be readily available. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN AND INTRAVENOUS CORTICOSTEROIDS AND AIRWAY MANAGEMENT INCLUDING INTUBATION SHOULD ALSO BE ADMINISTERED AS NECESSARY.

PRECAUTIONS: General. While PIPRACIL possesses the characteristic low toxicity of the penicillin group of antibiotics, periodic assessment of organ system functions including renal, hepatic, and hematopoietic during prolonged therapy is advisable. Bleeding manifestations have occurred in some patients receiving β-lactam antibiotics including piperacillin. These reactions have sometimes been associated with abnormalities of coagulation tests such as clotting time, platelet aggregation, and prothrombin time and are more likely to occur in patients with renal failure. If bleeding manifestations occur, the antibiotic should be discontinued and appropriate therapy instituted.

The possibility of the emergence of resistant organisms which might cause superinfections should be kept in mind, particularly during prolonged treatment. If this occurs, appropriate measures should be taken.

As with other penicillins, patients may experience neuromuscular excitability or convulsions if higher than recommended doses are given intravenously.

PIPRACIL is a monosodium compound containing 1.85 milliequivalents of Na^+ per gram. This should be considered when treating patients requiring restricted salt intake. Periodic electrolyte determinations should be made in patients with low potassium reserves, and the possibility of hypokalemia should be kept in mind with patients who have potentially low potassium reserves and who are receiving cytotoxic therapy or diuretics.

Antimicrobials used in high doses for short periods to treat gonorrhea may mask or delay the symptoms of incubating syphilis. Therefore, prior to treatment, patients with gonorrhea should also be evaluated for syphilis. Specimens for darkfield examination should be obtained from patients with any suspected primary lesion and serologic tests should be performed. In all cases where concomitant syphilis is suspected, monthly serological tests should be made for a minimum of four months.

As with other semisynthetic penicillins, PIPRACIL therapy has been associated with an increased incidence of fever and rash in cystic fibrosis patients.

Drug Interactions. The mixing of PIPRACIL with an aminoglycoside *in vitro* can result in substantial inactivation of the aminoglycosides.

Pregnancy—Pregnancy Category B. Although reproduction studies in mice and rats performed at doses up to four times the human dose have shown no evidence of impaired fertility or harm to the fetus, safety of PIPRACIL use in pregnant women has not been determined by adequate and well-controlled studies. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. It has been found to cross the placenta in rats.

Nursing Mothers. Caution should be exercised when PIPRACIL is administered to nursing mothers. It is excreted in low concentrations in milk.

Pediatric Use. Dosages for children under the age of 12 have not been established. The safety of PIPRACIL in neonates is not known. In dog neonates dilated renal tubules and peritubular hyalinization occurred following administration of PIPRACIL.

ADVERSE EFFECTS: PIPRACIL is generally well tolerated. The most common adverse reactions have been local in nature, following intravenous or intramuscular injection. The following adverse reactions may occur:

Local Reactions. Thrombophlebitis (4%), pain, erythema, and/or induration at the injection site (2%) and, less frequently, ecchymosis, deep vein thrombosis, hematomas.

Gastrointestinal. Diarrhea and loose stools (2%); less frequently, vomiting, nausea, increases in liver enzymes (LDH, SGOT, SGPT), hyperbilirubinemia, cholestatic hepatitis, bloody diarrhea, and, rarely, pseudomembranous colitis.

Hypersensitivity Reactions. Anaphylactoid Reactions (see WARNINGS). Rash (1%); less frequently, pruritus, vesicular eruptions, positive Coombs tests.

Renal. Elevations of creatinine or BUN and, rarely, interstitial nephritis.

Central Nervous System. Headache, dizziness, fatigue.

Hemic and Lymphatic. Reversible leukopenia, neutropenia, thrombocytopenia, and/or eosinophilia have been reported. As with other β-lactam antibiotics, reversible leukopenia (neutropenia) is more apt to occur in patients receiving prolonged therapy at high dosages or in association with drugs known to cause this reaction.

Serum Electrolytes. Individuals with liver disease, or individuals receiving cytotoxic therapy or diuretics, were reported rarely to demonstrate a decrease in serum potassium concentrations with high doses of piperacillin.

Skeletal. Rarely, prolonged muscle relaxation.

Other. Superinfection, including candidiasis
Hemorrhagic manifestations.

An Access-oriented Negotiated Fee Schedule

The Caterpillar Experience

RICHARD H. EGDAHL, M.D. and ROBERT D. HERTENSTEIN, M.D.

From the Department of Surgery and Health Policy Institute, Boston University Medical Center, Boston, Massachusetts, and Caterpillar Corporation, Peoria, Illinois

This paper describes the system used by Caterpillar Corporation (CAT) in Peoria, Illinois, to reimburse surgeons. The CAT system assures access for Caterpillar employees and their families to a selection of qualified surgeons, while achieving cost savings through improvements in processing of surgical claims and negotiation of selected fees. CPT-4 codes are recoded for greater accuracy, when indicated, surgical services that have been incorrectly unbundled are rebundled, and the appropriateness of surgical assistant charges is reviewed. A "degree of difficulty" relative value scale (DODRVS) of surgical services is periodically revised as technology changes. The DODRVS multiplied by a regional factor, determined by local market research, establishes the fee that CAT will pay the surgeon. Balance billing is permitted if the patient (1) is informed in advance by the surgeon that the fee will be higher than CAT will pay, and (2) knows that the service can be obtained from other local surgeons who will accept the CAT fee. The goal of the CAT method of surgeon reimbursement is to gain physician support for an access-oriented, market-driven negotiated fee schedule. Compared with a resource-based relative value scale (RBRVS) methodology, the CAT system is not formula-driven and depends on physician acceptance.

FOR MORE THAN 25 years, physicians have benefited from a generous fee-for-service system of payment. However, between 1965 and 1985, national expenditures for physicians' services have increased almost tenfold, from $8.5 billion in 1965 to $82.8 billion in 1985.[1] As a result, several possible physician payment reforms are being considered. Prospective payment by diagnostic-related groups (DRGs), put in place to control Medicare hospital expenditures, is a fact of life for hospitals. Medicare and Medicaid are now pushing for changes in the way they pay physicians. Managed care programs are negotiating discounts from all types of health care providers.

Reform activity can be identified on many fronts: (1) Congress has frozen Medicare fees, effective June 1984 through January 1987. Congress' intent is now to shift the burden of effectively constraining the growth of Medicare Part B costs to providers rather than Medicare beneficiaries. (2) The Physician Payment Review Commission, created by Congress, has issued a recent major report, outlining ways that physicians could be reimbursed under Medicare in the future.[2] (3) In fall 1985, the Health Care Financing Administration (HCFA) contracted with Harvard University to conduct a 30-month study of resource-based relative value scales (RBRVS) for physician services.[3] This system is being developed under the direction of William Hsiao, Ph.D., Harvard School of Public Health. The American Medical Association is a subcontractor on the study for HCFA. The study is scheduled to be completed in July 1988. (4) The Massachusetts Rate Setting Commission is revising its Medicaid fee schedule, based on the RBRVS, for planned application in mid-1987. (5) The Massachusetts Insurance Commissioner asked Blue Shield to consider reforms in physician payment, with an emphasis on developing an RBRVS, as a condition of his approving a Blue Shield rate increase in 1987. (6) Congressional hearings on physician fee schedules continue, and congressionally sponsored studies of physician fees have recently been published.[4,5]

Within the administration in Washington, proponents of physician fee reform are calling for an expanded use of capitation in the long term, or some form of physician DRGs.[6] But these changes are not imminent. During the next several years, fee payment modifications will be based in fee-for-service recalculations. If the revised physician fee schedules achieve acceptable levels

TABLE 1. *Medicare Prevailing Fees* ($, 1984)*

State	CABG	Appendectomy	Cataract
New York	6000	1134	1547
Michigan	3100	399	825
Rhode Island	2587	516	928

* The charges indicated are for specialists and for the large urban areas within the states listed.

From the U.S. Department of Health and Human Services, Health Care Financing Administration. Medicare Directory of Prevailing Charges 1984. Washington DC: U.S. Government Printing Office, 1984.

of patient access and physician support, they will be part of the blueprint for future health care delivery in both private and public arenas.

Background

Medicare's "customary, prevailing, and reasonable" (CPR) payment system is, by general consensus, unsatisfactory in today's competitive market in health services. There are many problems associated with CPR. It tends to be inflationary and slow to respond to alternatives in technology and changes in both availability of physicians and need for services. Some charges appear excessive to most observers, even taking into account geographic cost-of-living variations and other variables. For example, under Medicare, the cost of a triple vessel CABG (coronary artery bypass graft) in New York in 1984 was $5500. The cost of this same procedure in Michigan was $3100 and $2587 in Rhode Island (Table 1).

Similar variations are found in fees from the private sector. For example, unexplained fee variations exist in managed health care models such as independent practice associations (IPAs). Hip replacement at three different IPAs in the eastern part of the country ranged from $2808 to $4274 (see Table 2).

Noting these wide discrepancies, the federal government and a number of large private purchasers of health services have turned their attention to the ways physicians are compensated for the care they provide. Fundamental changes in the methodology of physician reimbursement are being discussed. Serious consideration is being given to systems that would pay physicians by capitation or by including the physician payment with the hospital DRG payment. However, both options represent a radical departure from the current system and are viewed as politically unrealistic, at least in the short term.

TABLE 2. *Fee Variations in 3 IPAs, 1986 Fees ($)**

Operation	Plan #1	Plan #2	Plan #3
Appendectomy	645	950	1111
Cholecystectomy	1055	1465	1710
Cataract removal	1280	1650	1980
Hip replacement	2808	3666	4274
CABG (3-vessel)	4690	6123	7139

* Plan names withheld because fees were given in confidence to Health Policy Institute by IPA executives.

Several interim remedies are being devised, however. One approach adjusts a few fees that are grossly out of line. Invoking "inherent reasonableness" authority, HCFA uses this approach to reduce payments for "overpriced" procedures. Although corrections have been made for a few services such as cataract removal and installation of pacemakers, most physician payments currently are based on historic trends.

Another approach used by HCFA to control "runaway" costs involves a recalculation of the Medicare Economic Index (MEI), an inflation index for increases in physician office expenses that result from inflation.[7] HCFA estimates that this downward modification in the MEI will save Medicare an increasing amount of money.

Another approach, more far-reaching in concept than the interim measures described previously, but less radical than capitation and physician DRGs, was tried by the Boston University Health Policy Institute (BUHPI) in the fall of 1984.[8] BUHPI compiled a group of 12 Massachusetts surgeons in a pilot effort to develop a complexity-severity index (C/S index) of surgical services, based on professional judgment, that could provide the basis for a relative value scale.

Building this kind of index, although intuitively appealing, proved time consuming and cumbersome. It also raised questions of antitrust. The Federal Trade Commission has barred professional groups from developing relative values guides on the grounds that such guides ". . . established by competitors in a commercial context, probably would constitute illegal price fixing because the dissemination of information and agreement on establishment of price structures usually lead to price uniformity and stabilization."[9]

In this pilot study, BUHPI identified a private corporation that had captured the essence of the C/S index and developed a practical way to convert it to a physician payment management system. The approach of Caterpillar Corporation (CAT), based in Peoria, Illinois, has resulted in the evolution of "degree of difficulty" relative value scales (DODRVS) and regional multipliers that appear to accomplish a pragmatic fee schedule reform. Access to physicians is achieved for CAT employees and their families, and local physician acceptance of the overall CAT process is maximized. Since CAT is not a dominant payer in any geographic area and is not a provider, the potential for antitrust challenges is minimal.

Table 3 shows the close correlation between the C/S index numbers, arrived at through the BUHPI study, and CAT's DODRVS, reached by consultation with regional surgeons. This striking correlation between the two processes suggested to the BUHPI that CAT was on target in its surgical fee activities, and led to the collaborative project described in this paper.

TABLE 3. *BUHPI C/S Index Compared with CAT DODRVS*

	C/S Index	DODRVS
Thoracentesis	3	3.4
Appendectomy	24	26.4
Cholecystectomy (with common bile duct exploration)	48	47.7
Total thyroid lobectomy	40	41.3
Modified radical mastectomy	45	47.7
Colectomy, partial	55	54.5
Pancreatoduodenectomy	100	100.0

The Caterpillar Method

CAT is an international manufacturer of earthmoving machinery and equipment, employing an estimated 54,000 employees in 15 domestic and 13 foreign plants. CAT health benefits cover employees and dependents, as well as 21,000 retirees. The benefit package includes hospitalization, physicians' services, laboratory, x-ray, prescription drugs, and dental and eye care. The CAT health plan is self-insured and self-administered.

In 1983, CAT implemented for its U.S. employees a negotiated fee schedule approach to physician fees for surgical and invasive procedures. The CAT physician payment system emphasizes (1) employee access to a wide range of qualified surgeons, (2) fees negotiated with local surgeons that are considered reasonable and consistent with local market forces, and (3) billing practices review applied consistently to all incoming claims. Particular features of this approach are described below.

Establish a fair fee cap. With input from respected community physicians in locations with a large number of CAT employees, CAT establishes a fair fee cap for surgical services. The CAT method involves convening a limited number of meetings with selected representatives of the surgical community and the CAT medical director for group insurance (CAT M.D.). Where it makes the most efficient use of time, the CAT M.D. meets with individual specialty groups. Operating under a "physician friendly" philosophy and the assumption that physician education and involvement help achieve a mutually agreeable solution, the CAT M.D. describes the situation from CAT's point of view: (1) there are wide variations in fees and billing practices; (2) there is often insufficient documentation to properly process claims; (3) a way is needed to compare the difficulty of various services so their "relative value" can be considered for payment decisions; and (4) a reassessment of the need for surgical assistants is needed.

Actual claims received are used as examples (with patient and provider identities protected). The CAT M.D. then solicits provider input on how problems can be corrected. General consensus is gained on reasonable billing practices and relative degree of difficulty of various procedures, based on recommendations by the CAT M.D. and discussions with physician groups.

Use of geographic multipliers. CAT's DODRVS is combined with a regional dollar multiplier to calculate the actual dollar payment limit. The regional multiplier is based on market research by the CAT M.D. Where there are unusual market conditions for certain specialties, CAT may adjust the multiplier up or down for some services rather than changing the entire region's multiplier. This system allows CAT to take into account the local health care market, legitimate variations in provider billing and medical practices, and variations in the cost of living.

Continual audit and recoding of physician bills. CAT claims processors subject each incoming physician bill to a coding analysis of CPT-4 codes as a first step, and recode claims where irregularities are found. Obvious simple coding errors are corrected first. Individuals with clinical knowledge and judgment then compare the provider's description of services with submitted codes; operative reports are requested for most surgical claims and follow-up calls to provider offices for clarifying information are common. Once the claim reviewer is satisfied that enough information is available to code the bill consistent with CAT procedures, recoding is finalized, and the correct codes are compared with established regional fee schedules. Reviewers with clinical experience consult the CAT M.D. as needed, assuring that a high level of understanding of the surgical experience is applied in the review process.

Tables 4–7 illustrate some features of the CAT process. They are representative of some claims received by CAT.

In Table 4, the appropriate payment is $1000 for code 38100. The patient was hospitalized for an elective splenectomy. The CAT reviewer would disallow codes and

TABLE 4. *Bundling of "Unbundled" Bill*

Procedure	CPT Code	Charge
Splenectomy	38100	$1000
Laparotomy	49000	600
Appendectomy	44950	600
Preoperative check (in hospital)	90215	125
Suture removal	90270	100
Total charge		$2425
Amount paid		$1000

TABLE 5. *Excessive Fee Reduced, Assistant Surgeon Claim Denied as Not Medically Necessary*

Procedure	CPT Code	Charge
Excision biopsy, breast (R)	19120	$1500
Excision biopsy, breast (L)	19120-50	1500
Charge		$3000
Assistant surgeon fee (R)	19120-80	$1200
Assistant surgeon fee (L)	19120-50-80	1200
Charge		$2400
Total charge		$5400
Amount paid		$ 750

charges for all except the splenectomy: a charge for laparotomy and incidental appendectomy is warranted only if done as a separate procedure and preoperative check and postoperative care are conventionally part of the global surgery fee. A charge of $1000 for the splenectomy is in line with the regional fee schedule and is the amount ultimately approved.

In Table 5, the appropriate payment is $750 to the primary surgeon for code 19121 (excision biopsy, breast, bilateral). Under most conditions, one surgeon can perform a breat biopsy. The operative report indicates no unusual circumstances. The assistant surgeon is not reimbursed, and the patient is informed of CAT's review decision.

In Table 6, the appropriate regional payment is $60 for code 17100. The procedure was actually a simple wart removal. The operative report describes a 0.25-inch plantar wart on one foot. Excision combined with use of the laser constitutes excessive treatment for this common condition. Wart removal is most accurately coded as 17100 ("destruction by any method of benign skin lesion").

CAT knows that four local experienced, board-certified cardiac surgeons will carry out a three-vessel coronary artery bypass for $5000, assuring that access can be achieved for that fee (Table 7).

Tables 4–7 demonstrate that complete and knowledgeable recoding of claims requires familiarity with both the content of various surgical procedures and the details of coding surgical services.

Physician negotiations. Individual physician negotiations are carried out for selected claims. After establishing an overall fee schedule with local physician representatives, CAT continues its negotiations on a selected claim-by-claim basis. If the amount charged for corrected codes significantly exceeds the regional fee cap, CAT contacts the billing physician, giving information on the corrected codes and the amount allowed. The CAT M.D. makes many of these calls. Usually the provider is willing to accept CAT's recoding and reduced fee. Discussions of claims with physicians have revealed that providers enter practice largely ignorant of common billing practices. Most admit they do not know what various procedures are worth. At best they occasionally may ask other providers what they charge. Those who use an RVS have access only to a wide variety of unstandardized sources. Some are advised to start charging high rates to get a high fee profile. Often, physician offices have an office clerk coding claims who is not trained in medical terms or coding, whereas other physicians rely on central billing services that promise to "maximize reimbursement," often with "creative" upcoding or unbundling of services.

TABLE 6. *Recoding of Unnecessary Procedure, Excessive Fee Reduced*

Provider Description	CPT Code	Charge
Excision, benign lesion, foot and use of CO_2 laser	11421	$450
Total charge		$450
Amount paid		$ 60

TABLE 7. *Fee Adjustment*

Procedure	CPT Code	Charge
Coronary artery bypass graft, 3 vessel	33512	$8000
Total charge		$8000
Amount paid		$5000

Employee communication. CAT has a program of employee communication that defines the employees' responsibilities and options when payment is less than the fee charged by a surgeon. A letter of explanation is automatically generated to the employee when there has been a payment reduction. It states that if the employee has discussed the fee with the physician before the procedure, the employee is responsible for the amount in excess of CAT's fee cap. Also, employees are told when their provider has agreed to accept CAT's reimbursement as payment in full.

Patient held harmless. If a physician bills an employee for the amount that exceeds the fee cap, the employee is instructed to contact CAT, and a CAT provider relations specialist discusses the situation with the physician. Patients are not required to pay the physicians' balance bill above the CAT payment (that is, they are "held harmless") if the physicians have not informed the patients of the higher-than-cap fee before the procedure. CAT intervenes on the patient's behalf when the physician refuses to lower his/her fee to the established cap. On average, of about 20,000 physician claims received per year, CAT has less than a dozen instances in which providers insist on trying to obtain reimbursement above the CAT fee through claims court. In over 95% of these cases, the judge has agreed that CAT's payment is reasonable for the services, based on local surgeon input.

Study of Savings with CAT Method

CAT's internal calculations indicate that it achieves significant savings with its surgeon bill review process by reducing fees that otherwise would have been paid in full. The BUHPI is conducting an external evaluation of the CAT process for managing surgeon fees. Standard surgical fee processing by large insurance companies and third-party administrators is being compared with the potential cost savings of the CAT process. The BUHPI has obtained samples of consecutively filed claims for surgical services that have been processed for several large self-insured corporations that administer their claims through major insurance carriers. The benefit plans establish payment caps at a percentile of usual and customary fees, and the carriers' auditing of codes was representative of current industry standards. CAT's recoding and bundling procedures, as well as payment caps, were applied to these claims, with the goal of finding if the savings from payment reduction significantly exceeded those achieved by these carriers.

Hard copies of the providers' originally submitted claims were processed by CAT staff without information about changes from charges that had been made by the carriers before these claims had been paid. Confounding variables of payment due to copayments, deductibles, or coordination of benefits were eliminated.

The total charges included in the sample claims were over $140,000. The carriers adjusted 13 to 15% of their claims and paid 4.3 to 35% less than total charges. CAT adjusted 35 to 40% of these same claims and reduced payment from charges by 22 to 43%. Therefore, CAT would have achieved an additional savings of 8 to 17.7% if CAT's procedures and the lower of CAT or the administrator's fee schedule were used. One third of the additional savings came from coding changes in the original bills and two thirds by the application of the CAT negotiated fee schedule. In some instances providers submitted an incorrect code that significantly *undervalued* the procedure that was done. If the provider's code had been used, the payment would have been cut to an unreasonable level. In these instances, the CAT reviewer "upcoded" to the correct code and allowed the more appropriate fee; the savings potential includes these corrections in favor of billing surgeons.

Discussion

The CAT system for managing surgeons' fees has been developed by a progressive benefit department in a large American corporation. The system depends on detailed knowledge of surgical practice so that recoding and bundling of procedures categorized by CPT-4 codes can be accurately carried out. It requires contact with local surgeons in regions with a high concentration of employees so that market forces can be taken into account in determining an appropriate level of local fees.

An access-oriented negotiated fee schedule can have many permutations. In areas with a surgeon surplus, a corporation may be able to negotiate lower fees with surgeons than those previously paid. In areas with few surgeons, fees lower than customary are more likely to create patient access problems should the surgeons resist reductions negotiated elsewhere. Still, modified versions of CAT's approach would be similar to processes already used by the government in establishing "inherent reasonableness" for cataract extraction and pacemaker installation fees.

The key concern about any new surgeon payment approach should be the ability to attract a good representation of local surgeons who will accept it. Ensuring employees' access to qualified surgeons is the paramount goal. All other considerations, even inherent reasonableness of lower fees because of technological advantages or cost containment, should remain secondary.

Based on the BUHPI's analysis, the CAT process is a workable and market-tested solution to the need to balance access and cost management. It is suitable for large corporations such as CAT with both self-funded and self-administered health benefits. It can also be used (after eligibility is certified and benefits are coordinated) by claims processing systems. Accurate implementation of the CAT process requires (1) hard copies of the CPT-4 codes submitted by the surgeon and availability of the operative notes, to reconcile discrepancies between CPT-4 codes and the surgical service, and (2) access-oriented negotiated fee schedules obtained by applying a geographic multiplier to an RVS, such as CAT's DODRVS.

State and federal governments can modify the CAT process for Medicaid and Medicare, with the same goals that motivate the private sector: access and cost management. Regional fee schedules could be established with national DODRVS values and regional multipliers based on market forces. Balance billing is optional, using the CAT model. However, its effectiveness as a cost management approach is strengthened with its "hold harmless" provision. In the CAT system, if a patient knows a surgeon is charging a fee higher than the negotiated fee, the patient is responsible for the balance. If no discussion has occurred, the patient is held harmless for bills in excess of the fee cap.

If adequate access is to be preserved without the need for balance billing, payments must be established so that a majority of qualified surgeons in each region will accept the negotiated fee as payment in full. If this acceptance is not achieved, then access problems will arise, as

TABLE 8. *Comparison of "Resource-based Relative Value Scale" (RBRVS) and "Access-oriented Negotiated Fee Schedule" (AONFS) for Physician Reimbursement**

	RBRVS (Hsiao)	AONFS (CAT)
Goal	A "comparable worth" reform for physicians, a group with high incomes relative to most other occupations.	Patient access to local physicians at a negotiated price.
Methodology	Complex formula determines RBRVS; time is a major determinant.	Revision of fees is based on negotiations, M.D. fee acceptance patterns (market forces, not payment of charges).
Application	Two basic problems: (1) RBRVS is not a fee, and knowledge is needed of regional situations to use multiplier effectively, (2) when applied in Massachusetts, shown to need extensive modification to get support of, and access to, local surgeons.	In routine use. CAT knows that well-qualified local physicians will accept the AONFS.

* AONF = DODRVS × regional multiplier.

occurred in 1986 for the Massachusetts Medicaid program. That program was forced to increase significantly its fees for normal deliveries. As stated in the *Boston Globe*, ". . . responding to a crisis in access to obstetrical care in many areas of the state, the panel hiked the all-inclusive fee for pregnancy care and childbirth from $508 to as much as $1,200."[10] This is a good example of the futility of a fee schedule that does not build on knowledge of physicians' availability at different fee levels in each region. The Massachusetts Medicaid program had a previous experience with attempting to introduce a fee schedule based on a "resource-based" formula.

In July 1983, the *Boston Globe* described a new strategy that was suggested by the Massachusetts Rate Setting Commission for the Medicaid program and workers compensation.[11] Based on the 1979 study by Drs. Hsiao and Stason from the Harvard School of Public Health,[12] the Rate Setting Commission proposed that the fees for 21 common surgical procedures should be cut by amounts ranging from 4% to 59%. At the same time, physicians seeing patients in their office were to get 71% more for initial visits. These proposed changes were the estimated relative resource requirements of different physician services, with a strong focus on the time involved. The formulas were established in the Hsiao/Stason analysis of physician practices.

These changes were adopted in September 1983, but on August 23, 1984, the Rate Setting Commission raised the fees that the state Medicaid program paid to doctors for surgical procedures. As stated in the *Boston Globe*, "no prior hearing was held or public notice given before the August reversal because the Commission subsequently said physician resignations from Medicaid had reached the level of a public health emergency. Most striking of these defections were obstetricians/gynecologists."[13] This experience suggests that fees ultimately paid by Medicaid were primarily driven by the need to get access to Medicaid patients to physicians, and not by a formula for "resource costs."

The American Society of Internal Medicine and the American Medical Association have supported an elaborate study of the Hsiao methodology commissioned by HCFA, and there is much speculation about the possible use of an RBRVS for the determination of Medicare fees when it becomes available in the summer of 1988. The investigators of the BUHPI originally believed that the consensus process to determine a C/S index could be developed as the basis for fee reform that would be acceptable and perceived as fair by physicians. However, the consensus approach is laborious, and much time would have been necessary to interrelate all specialties and resolve potential conflicts. It was then that the BUHPI began to study the CAT system, and found that it involved a process with appropriate goals, methodology, and application for cost management and market acceptance.

Table 8 outlines the basic differences between a "resource based" RVS and an access-oriented negotiated fee schedule, as used by CAT. A basic goal of the RBRVS is to "reform" physician reimbursement in the direction of more equity between procedure-oriented specialists and generalists. However, as the evidence suggests, this goal will be in conflict with realities of the marketplace and will result in paying fees that are either unnecessarily high or too low to get ready access for insurees to local physicians.

The methodology of the RBRVS is based on a formula unrelated to local market forces, whereas the access-oriented negotiated fee schedule used by CAT builds on negotiations and local fee acceptance patterns to gain access. The CAT system's ability to adjust for regional differences in the market is the essential difference in the two approaches. The CAT system is in routine use and will continue to be modified by changes in local physician manpower and other factors such as increases in malpractice premiums. We suggest that an access-oriented negotiated fee schedule such as the CAT system deserves consideration as the preferred method of fee reform.

DISCUSSION

DR. W. GERALD AUSTEN (Boston, Massachusetts): I congratulate Drs. Egdahl and Hertenstein on an excellent and stimulating paper. They have worked long and hard on physician payment reform, and they recognized early the importance of physician acceptance in any proposed reform. Thus, a major element of the current proposal includes the active participation of the physicians.

Three and a half years ago, the Regents of the American College of Surgeons created a Committee on Physician Reimbursement of which I have been Chairman. This committee, with much input from the surgical specialty societies, has developed recommendations for the reform of the Medicare physician payment program, and these recommendations were approved by the Regents in October 1986.

The aim of the College, like the approach presented today, is to identify ways to achieve a more rational payment system with cost savings and at the same time ensuring adequate access to quality care.

The ACS approach has a number of similarities to the program presented this morning; the ACS proposal includes the creation of a Medicare relative value scale based on physician charge data and with modifiers based on geographic differences in practice costs, the definition of payment units with emphasis on a global fee and the creation of definitions and guidelines to determine when an assistant at surgery for Medicare payment purposes is necessary.

I have one question for the authors. The Caterpillar Corporation has approximately 50,000 employees in 15 domestic plants, and it also has a very persuasive, sensible medical director. How would you expand your proposal from one company to a national program?

Finally, I would like to add that it is crucial that surgery be involved as much as possible in the current debate on physician reimbursement reform, and we need to be able to present sensible and fair approaches backed by solid data. The next year and a half is probably going to be crucial.

I would urge Drs. Egdahl and Hertenstein to continue to gather information and to make every effort to present their data and recommendations to the appropriate congressional committees and to the Administration.

DR. OLIVER H. BEAHRS (Rochester, Minnesota): Drs. Egdahl and Hertenstein have done us a favor by developing and reporting a modification of the CPR fee for service reimbursement for surgical services. I appreciate the opportunity to have read the manuscript.

Their program, which is a negotiated access RVS, is in contrast to the Harvard–AMA resource based RVS, and is being developed under contract from HCFA. This RVS is of concern because of the inordinate weight given to time as a factor and the methodology being used.

There is great anticipation regarding this study in Washington and some are thinking of it as the only game in town.

The Physician Payment Review Commission (PhysPRC) established by Congress in 1986 made its first report to Congress on March 1, 1987. The Commission supports a fee scale based on a national RVS with appropriate regional multipliers to determine fees. The basis for the RVS has not been determined, but hopefully it might be based somewhat on historic charges and not the strictly resourced criteria of the based parameters used in the Harvard Study.

The use of the CPT-4 Code has come under criticism: first a dictionary of 2000 codes, and now 7000 and with multipliers 48,000. It was established primarily for medical record keeping not to establish charges. It has led to unbundling of services and upcoding to establish fee for services. This practice has led to excessively high fees in at least 10% of cases because of unbundling or upcoding.

I would be interested in the author's suggestions how the CPT-4 codes might be collapsed or bundled and what policy could be established to prevent these abuses.

A long-term program for physician payment is probably several years away and may be a fee scale hopefully, but there is administrative and congressional support for capitation or voucher arrangement, possibly DRGs. Congress is looking for a near-term solution to its budget problem for 1988.

The budget mark-up will be in the next few weeks and the recommendations to meet the cut almost certain in physician reimbursement will be in place by September.

The reduction in reimbursement might be another freeze, a shaving downward of the medical economic index, selecting the high-cost outliers such as coronary artery bypass, hip reconstruction, and/or TUR for across-the-board decreases as was done to cataract surgery in 1986 and 1987, or selective decrease in the high rollers or by addressing the reduction by using the inherent reasonable rule that is already in legislation.

My second question to Dr. Egdahl and Dr. Hertenstein is: what are your recommendations in the next month or two to meet the 1988 budget limits?

DR. MARTIN ALLGÖWER (Basel, Switzerland): I appreciate the invitation to look "with a Swiss eye" at the presentation of Dr. Egdahl.

In Switzerland it is said that the surgeon goes through two stages: At the beginning of his career, collecting a fee, he gets red in the face. Later on his face reddens when he does not get paid!

The Swiss economic system is a rather complex mixture of free enterprise and institutions run almost exclusively by public bodies. We consider many of the things you do not as public responsibilities. These include post and telephone services, railway services, schooling and university formation, and most hospitals are run by local government agencies. The health care system is furthermore complicated by the fact that insurance conditions for accidents are very different from those for diseases. It is obvious that this difficult distinction keeps our lawyers busy!

Basically, surgeons are mostly employed on a geographical full-time basis in a state hospital. Those state hospitals, however, have private, semiprivate, and general wards. This, I believe, is a rather favorable arrangement, combining a salaried position for the administrative obligations as well as for the care of the general patient with a fee-for-service system for the private patients. Now, comparing this with the cap system, we find great similarities because the Union of Swiss Surgical Societies, including all specialties, has set up a range of fees that may be reasonably asked from a patient or from the insurance, *i.e.,* the third party paying. Those ranges, just to give you an idea, would range from 400 to 1000 francs for an appendectomy, for a gallbladder from 1000 to 2000 francs, and for major operations such as a total gastrectomy, a Whipple, an acetabular repair or a resection of an abdominal aneurysm, from 3000 to 6000 Swiss francs. That is about the maximum fee we are allowed to ask or, at least, that the Union will support, if it is contested in court. You may divide the figures by 2 to arrive at dollar values, because that is about the realistic comparison in terms of buying power.

It is a fairly democratic self-regulating peer controlled system. What we dislike in Switzerland is the "big brother" state watching us and telling us what to do.

We have one advantage over you. The contingency system is unacceptable and the one party who loses "the battle" usually has to pay the other's legal expenses. That often prevents people from going to court, although there has been a definite increase in liability claims in recent years.

Overall our system results in an average income of some 300,000 to 400,000 francs for a Swiss surgeon. Out of that he pays some 50% in taxes. Our rather democratic system is similar to what Dr. Egdahl has just presented. It is based on a fee for service "common sense scale," the majority of surgeons working in a geographical full-time scheme.

DR. WILLIAM R. DRUCKER (Rochester, New York): I appreciate the opportunity I had to review this paper. Dr. Egdahl has given us a clear presentation of an industry-sponsored plan that attempts to gain physician compliance with a method of reducing costs of medical care through reduction in fees.

It is a very clear example that in addition to government today, our health care system is being strongly influenced by industry.

I have a couple of editorial comments and then a couple of questions. The major factor in the rise in health care costs is not physician fees. This is simply illustrated by a look at the average fees of physicians across the country, somewhere in the range of $50,000–$150,000. I realize that others make considerably more, but each physician can be estimated to cost the health care system something in the order of three quarters of a million dollars per year by the exercise of his physician rights in doing his job of taking care of patients. Therefore, the major target that needs to be addressed is physician behavior, not physician fees. Nevertheless, fees are perceived as a problem that is going to be addressed whether we like it or not.

I wonder whether this paper is simply the expression of a last gasp hope that current physician fees and the fee for service system will continue. I sincerely hope this is not its purpose and I believe Dr. Egdahl agrees based on the way he has presented the paper. My reading from the paper is that Dr. Egdahl is presenting a plan that is asking clearly for physicians to get together and plan to help solve the problem of fees rather than having it done for us by external agencies; that means industry and government.

My questions are these. They are straightforward, I believe, and can be answered simply. What will happen in the case of an emergency when one of the patients in the system under the cap must have an emergency operation and they seek a doctor who does not agree with the system: would this be settled in claims court?

What about quality? Does the system depend on the physician participants to ensure quality or do they have other ways to ensure that their employees are obtaining the quality of care that they would under the current system of fee selection.

How about comparison with other systems? Has there been enough experience to date to show that this system is gaining popularity? Is there any way to compare this system with others in terms of two factors: physician acceptance to work in the system, and employee acceptance of this system for their health insurance?

Then there is a question of cost. This is a very complex system. It seems very costly if one reads carefully. What is the cost? Is there any estimate of what the cost would be of setting up and maintaining this system that requires close scrutiny of all bills that come in; a very complex system of monitoring these bills? Is the billing method unique to CAT or can other insurance systems do this too? Is this system for sale? Do other insurance companies look at claims this carefully?

DR. BENSON B. ROE (San Francisco, California): Dr. Egdahl is to be thanked for bringing to our attention a sensible proposal to address a serious threat to the fee-for-service system. I believe we finally are all aware of this threat, and I am delighted that we are prepared to gather our forces to get behind something positive.

About 8 years ago I became aware of the enormity of the abuses to the current system that were taking place, perhaps not by the respectable members of our profession but by an alarming number of those who did the kind of unbundling and some of the things that he showed you. I published an article that was intended to stir us to take some initiative in this problem rather than hoping it would go away. I hope it is not too late.

It is equally important that we get behind some system that establishes fiscal integrity so that we do not jeopardize the precious and unique privilege that we have of self-governance. This privilege is threatened by the behavior of some of our colleagues who have abused the system and brought this problem to our attention.

In addition to the proposals that Dr. Egdahl has made, I believe we should place emphasis on the magnitude of responsibility to cover not only accessory procedures but complications. No one can tell me whether my complication was part of the patient's underlying disease or could possibly be one from some flaw in my technique or management. We should accept as a part of our primary responsibility the full scope of managing a patient from start to finish without throwing in extra for everything that can be imagined. If we had done that, we would have reduced our total cost to the public by at least 20%.

DR. JAMES R. JUDE (Miami, Florida): I rise because I am confronted by patients who are faced with billing problems after hospital discharge. One of the problems is the unbundling that Dr. Egdahl has brought up.

Ten years ago on an Ethics Committee of our local medical society we, out of hand, tossed unbundling out as a completely immoral approach to any type of billing. I did not believe it even could possibly exist any more, but there is more of a problem than just the bundling together of the surgical fee. The problem is much greater than that. We always keep our office open to speak to any patients about any problems, and it is very common for them to present with bills of what really amounts to an unbundling of the bills of other physicians who were involved in their treatment.

Most commonly this has applied to anesthesiology, which frequently approaches 50% of the surgical fee. It is not, however, only the anesthesiologists, it is also the internists, the radiologists, the pathologists, and possibly the cardiologists who are reading electrocardiograms. Patients receive an enormous number of bills from physicians, and so it is a total physician unbundling and not just a surgical fee unbundling that is occurring.

Some way or other we have to approach the problem whereby there will be some type of bundling together of all physician fees as a package.

As our President presented yesterday in his Presidential Address, many treatments that we do are not all surgical anymore, but rather a blending over into medicine, and medicine is delivering surgery and surgery is delivering medicine. Therefore, we should give a great consideration to the total care and the total charge.

Dr. Egdahl, what if anything have you considered about these other fees in respect to a global cap or other industry approaches to the total cost of care in surgery?

DR. JONATHAN E. RHOADS (Philadelphia, Pennsylvania): I listened to this paper with a great deal of interest. I would emphasize that if most people have a 50% overhead, that a 15% reduction in fee is a 30% reduction in take-home remuneration. That is well to keep in mind.

There is one aspect of the overhead that has gotten bigger and that is liability insurance. This in a way is the loose cannon on the deck, and when you have a fee schedule set, whether by government or by consent, and this expense is assumed to be something that the physician will pay, you have an unpredictable situation.

I raise the question and ask the authors if there is any precedent for malpractice insurance being billed on a per case basis or a percentage of the fee. No doubt this would require the insurance company to have access to one's tax returns and so forth to be sure that it was honest, but it would have certain great advantages. It would permit the young physician starting out to start out on his own, pay his share of the liability costs, but not be expected to pay immediately the same amount that a person would be paying who is doing 10 times as much work in the middle of his career.

Perhaps the far greater advantage in my belief is that this could appear and should appear as a separate item on the bill.

I can think of no way that would educate more of the public as to the true cost of liability insurance than to have a bill (operation $300, insurance $125, or whatever it might come to).

I rose to raise this issue and to ask the authors if they knew if there was any precedent for such a plan and to ask whether they believe there is any way this could be tried out before we get tied into a fee schedule system with an unpredictable cost for liability insurance.

DR. RICHARD H. EGDAHL (Closing discussion): Dr. Austen's question about the possibility of expanding the Caterpillar program as it now exists to a national level is an important one. The problem is that major national programs such as Medicare necessarily involve a large bureaucracy, whereas a private self-administered company such as Caterpillar does not require the same degree of routinization of operations and an easily replicated methodology. The country could certainly be divided into 6–12 regions, each consisting of several states. I do not know whether appropriate flexibility could be built into the management and technical components of the administrative structure which would be part of a national program.

Dr. Beahrs raises questions about the future use of CPT-4 codes and asks what we can do in the short range to control outlier Medicare fees. I believe we can use CPT-4 as long as we understand the basis for matching up the procedures that actually were carried out with the codes, and have some way to ratchet downward those charges that seem inappropriate. Certainly there are a few groups selling systems with the goal of achieving code creep, which is basically dishonest. On the other hand, the majority of codes that are incorrect represent simple errors based on the difficulty of each doctor's office knowing all the technicalities of coding. We can stick with CPT-4, but must match the operative note with the CPT-4 code, using physician judgment to determine if the code is appropriate. The short-term answer for HCFA is to expand the principle of inherent reasonableness, which thus far has been limited to a few surgical conditions. Another 20–30 big-ticket items that appear to be out of line could be revised downward or upward.

Dr. Martin Allgöwer from Basel talked about the Swiss system and the apparent success of physician-sickness fund negotiations. This type of negotiation, with the government playing a catalytic role, might have relevance to the U.S. system in the private sector. However, Medicare will probably demand a closer involvement in the process than exists in Switzerland, since the government is paying the bill directly.

Dr. Drucker asked a key question about what happens in emergencies under the Caterpillar system. Usually Caterpillar pays charges in emergencies, but also has a strategy involving clearance for appropriateness of treatment in emergencies, when there is time. If gross overcharges are billed, even for emergency situations, and local surgeons support that the charges are unreasonable, then payment of those charges can be challenged.

Dr. Roe discussed his analysis of fees, and raised the question about possible antitrust issues if physicians are in the position of commenting on the appropriateness of their fees. Industry does not want to see private medicine nationalized, but could turn on us if we do not cooperate in developing a rational method of physician reimbursement. The key to not raising antitrust issues is for surgeons to act as individual consultants to payers who determine those fees, such as large industry.

Dr. Jude asked about how to get our internist colleagues involved in the process of fee negotiations. We found in our complexity/severity work with the Massachusetts Chapter of the American College of Surgeons that we could relatively easily get consensus on the "relative value" or "complexity/severity" of surgical services among that group. We then talked to internists and achieved some preliminary agreements; for example, an "intermediate acute myocardial infarction," from the time a patient comes into the emergency room, is taken into the critical care unit, and discharged, appeared to be similar in complexity/severity to an uncomplicated cholecystectomy, from initial diagnosis through discharge from the hospital after surgery. Reimbursement for some general medical conditions can be converted into a global fee, but for many medical conditions it is a more difficult process than for surgical cases.

Finally, Dr. Rhoads talked about malpractice problems associated with surgery. I return to the principal goal of Caterpillar and its fee process, which is access for their employees and their families to a significant number of high-quality local surgeons. Overall, malpractice problems will probably get worse before they get better. A solution will flow from severe access problems in different parts of the country, and a realization by both legislators and the public that the ordinary rigors of surgical practice are being compounded manyfold by additional financial and psychological pressures from the omnipresent danger of malpractice suits. We suggest that the Caterpillar process of negotiating access-oriented maximal fees with local surgical groups represents a reasonable compromise between paying charges, on the one hand, and accepting a formulaic-driven fee schedule not negotiated with some local physicians with access as a goal, on the other hand.

Increases in malpractice premiums will result in increased surgical fees, or the public will not have available the surgeons that they want in the variety of practice sites and numbers of specialties that are desired. We have only a modest amount of time before HCFA and the Congress will take some kind of action on fees, as they have on hospital reimbursement under Medicare. Industry can be our strongest ally in achieving a workable system of access-oriented negotiated fees.

Improved Hospital Morbidity, Mortality, and Survival after the Whipple Procedure

DAVID W. CRIST, M.D., JAMES V. SITZMANN, M.D., and JOHN L. CAMERON, M.D., F.A.C.S.

From the Department of Surgery, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Between 1969 and 1986, 88 patients had a Whipple resection for adenocarcinoma of the pancreas (N = 50), ampulla (N = 19), distal bile duct (N = 10), and duodenum (N = 9). Forty-nine patients were men, 39 were women, and the mean age was 58 years (range: 34–84 years). The patients were divided into two groups on the basis of two different time periods: those operated on from 1969 to 1980 (N = 41) and those operated on from 1981 to 1986 (N = 47). There were no significant differences between the two groups in terms of mean age, sex distribution, duration of symptoms before presentation, or mean weight loss. Likewise, preoperative laboratory data were similar for both groups of patients. In addition, mean tumor size for patients with pancreatic cancer (3.5 cm *vs.* 3.2 cm) and patients with nonpancreatic periampullary cancer (1.9 cm *vs.* 2.2 cm) was similar in both groups, as was the incidence of positive lymph nodes. Among the 41 patients operated on during the first period, hospital morbidity and mortality rates were 59% and 24%, respectively. In contrast, hospital morbidity and mortality rates were 36% and 2%, respectively, among the 47 patients operated on during the recent period. During the recent period, more Whipple procedures were performed each year (7.8 *vs.* 3.4) and by fewer surgeons (3.4 operations/surgeon *vs.* 1.9 operations/surgeon). In addition, between 1981 and 1986, there were fewer total pancreatectomies (9% *vs.* 39%), fewer vagotomies (26% *vs.* 76%), and more pyloric-preserving procedures (30% *vs.* 0) performed compared with the earlier period. During the recent period, mean operative time (7.8 *vs.* 9.0 hours), mean estimated blood loss (1694 *vs.* 3271 mL), and mean intraoperative blood replacement (3.6 *vs.* 6.3 units) were all significantly less than in the earlier period. These findings suggest that the recent decline in operative morbidity and mortality may be due to fewer surgeons performing more Whipple resections in less time and with less blood loss. The actuarial 5-year survival rate for the 38 patients with nonpancreatic periampullary cancer was 34%. Surprisingly, the actuarial 5-year survival rate among the 50 patients with pancreatic cancer was 18%. Moreover, in the absence of positive lymph node involvement, the 5-year actuarial survival rate among patients with pancreatic cancer was 48%. No explanation is obvious for the improvement in survival among patients with pancreatic cancer.

THE FIRST SUCCESSFUL RESECTION of a periampullary carcinoma in the United States was performed by Halsted in 1898.[1] The tumor was merely excised locally, and the patient died 7 months later of tumor recurrence. Whipple and colleagues,[2] in 1935, described the first pancreaticoduodenectomy performed for a periampullary carcinoma. The procedure was performed in two stages. The operation subsequently underwent modifications, and was first reported as a one-stage procedure by Trimble and Associates[3] in 1941. Thereafter, the pancreaticoduodenectomy became the operation of choice for patients with cancer of the head of the pancreas, ampulla, distal bile duct, and duodenum. However, during the 1960s and 1970s, some suggested that the Whipple procedure should be abandoned for the management of pancreatic cancer because of a high operative mortality rate, and virtually no long-term survivors.[4–6] Recently, several reports have suggested a sharp decrease in morbidity and mortality for the Whipple procedure,[7–9] as well as significantly improved survival for all periampullary tumors, including adenocarcinoma of the pancreas.[9,10] We have reviewed the experience with the Whipple procedure over an 18-year period at the Johns Hopkins Hospital to determine whether similar trends were evident in our patients.

Clinical Material

Between January 1969 and May 1986, 108 patients had an elective Whipple resection at the Johns Hopkins Hospital. Periampullary carcinoma was the indication

---

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

for surgery in 88 of the 108 patients. Of these 88 patients, there were 50 with adenocarcinoma of the head of the pancreas, 19 with adenocarcinoma of the ampulla, 10 with adenocarcinoma of the distal bile duct, and nine with adenocarcinoma of the duodenum. The remaining 20 patients had pancreaticoduodenectomy for a variety of other benign and malignant diseases, and were excluded from this review.

Of the 88 patients with periampullary tumors, 49 were men and 39 were women (Table 1). Sixty-eight patients (77%) were white and 20 (23%) were black. The patients ranged in age from 34 to 84 years with a mean age of 58.4 years. Jaundice was the most common presenting symptom and was present in 72 patients (82%). Weight loss occurred in 66 patients (75%). Mean weight loss for these 66 patients was 14.4 ± 1.6 pounds. Abdominal pain was present in 46 patients (52%). The mean duration of symptoms before hospitalization was 8.1 ± 1.2 weeks. Physical findings included hepatomegaly in 28 patients (32%), a palpable gallbladder in 20 patients (23%), and a palpable abdominal mass in three patients (3%). A previous history of adult onset diabetes of at least 2 years' duration was present in 13 patients (15%). Two additional patients (2%) had new onset diabetes mellitus. Eight patients (9%) had a history of significant coronary artery disease and six patients (7%) had chronic obstructive pulmonary disease. Fifteen patients (17%) had had a recent laparotomy before referral to this hospital. Mean laboratory data (Table 1) on admission to the Johns Hopkins Hospital included a hematocrit of 37%, white blood cell count of 8100, total lymphocyte count of 1854, a bilirubin level of 9.4 mg/dL, alkaline phosphatase level of 510 IU/L, SGOT of 163 IU/L, serum albumin level of 3.7 g/dL, prothrombin time of 12.4 seconds, and serum creatinine level of 1.04 mg/dL.

In an effort to detect recent trends in operative mor-

TABLE 2. *Operative Data for Patients Undergoing Pancreaticoduodenectomy**

	1969–1986 (N = 88)	1969–1980 (N = 41)	1981–1986 (N = 47)	p
Operation performed				
Total pancreatectomy	20 (23)	16 (39)	4 (9)	<0.01
Partial pancreatectomy	68 (77)	25 (61)	43 (91)	<0.01

bidity and mortality, the patients were divided into two groups on the basis of two time periods: those operated on between 1969 and 1980, and those operated on between 1981 and 1986. Forty-one patients were operated on during the first period, and 47 patients had a Whipple resection during the recent period.

Comparison of the two groups revealed no significant difference in terms of mean age, sex distribution, race, presenting symptoms, duration of symptoms, physical findings, or associated medical illnesses. Moreover, all preoperative laboratory data were similar in both groups of patients (Table 1).

Operative Management

Among the 88 patients, 68 (77%) had a Whipple operation that included resection of the head, neck, and uncinate process of the pancreas (Table 2). The remaining 20 patients (23%) had a Whipple operation that included a total pancreatectomy. Of the 20 patients managed by total pancreatectomy, 16 had carcinoma of the pancreas, two had carcinoma of the distal bile duct, one had carcinoma of the ampulla, and one patient had duodenal carcinoma. A pyloric-preserving Whipple procedure was used in 14 of 88 patients (16%). A truncal vagotomy was performed in 43 of 88 patients (49%).

The management of the pancreatic remnant varied according to the preference of the surgeon. In 55 (81%) of 68 partial pancreatectomies, a pancreaticojejunostomy was constructed by invagination of the pancreatic remnant into the jejunum, usually in an end-to-end fashion. Five additional patients (7%) had a mucosa-to-mucosa anastomosis between the pancreatic duct and jejunum. In eight patients (12%) the pancreatic duct was ligated and the pancreatic remnant oversewn without the formation of a pancreatic-enteric anastomosis.

Over the 18-year period, the mean operative time for all 88 patients was 8.4 ± 0.24 hours, the mean estimated blood loss was 2519 ± 263 mL, and the mean intraoperative transfusion requirement was 4.9 ± 0.40 units (Table 2). Compared with the 20 patients managed by total pancreatectomy, mean operative time was significantly less for the 68 patients treated by a partial pancreatectomy (9.5 ± 0.52 hours *vs.* 8.1 ± 0.25 hours, $p < 0.05$). However, mean intraoperative blood loss (3014 ± 464 mL *vs.* 2286 ± 312 mL, $p = 0.10$) and mean intraoperative transfusion requirement (5.9 ± 0.65 units *vs.* 4.7 ± 0.48 units, $p = 0.11$) were not significantly different between the two groups.

Mean tumor diameter was 3.4 ± 0.15 cm for the 50 patients with adenocarcinoma of the head of the pancreas and 2.1 ± 0.20 cm for the 38 patients with adenocarcinoma of the ampulla, distal bile duct, and duodenum. Pathologic examination of the resected specimen revealed positive regional lymph nodes in 37 of the 50 patients (74%) with adenocarcinoma of the pancreas and 19 of the 38 patients (50%) with adenocarcinoma of the ampulla, distal bile duct, and duodenum (Table 3).

When one compares the two periods, there were a number of differences in the operative management of the two groups of patients (Table 2). Between 1969 and 1980, total pancreatectomy was performed in 16 of 41 patients (39%), whereas only four of 47 patients (9%) had total pancreatectomy during the recent period ($p < 0.01$). A pyloric-preserving Whipple procedure was performed in 14 of 47 patients (30%) operated on between 1981 and 1986, whereas no pyloric-preserving procedures were done during the earlier period. A truncal vagotomy was performed in 31 of 41 patients (76%) operated on between 1969 and 1980, whereas only 12 of 47 patients (26%) had a vagotomy during the recent period ($p < 0.01$).

Between 1981 and 1986, mean operative time (7.8 ± 0.31 hours *vs.* 9.0 ± 0.34 hours, $p < 0.05$), mean estimated blood loss (1694 ± 281 mL *vs.* 3271 ± 440 mL, $p < 0.01$), and mean intraoperative blood replace-

ment (3.6 ± 0.37 units *vs.* 6.3 ± 0.65 units, $p < 0.01$) were all significantly less than in the earlier period. In addition, during the recent period, there were more Whipple resections performed each year (7.8 *vs.* 3.4) and by a fewer number of surgeons (3.4 operations/surgeon *vs.* 1.9 operations/surgeon). Comparison of the pathologic specimens for the two periods, however, revealed no significant differences between the two groups in terms of tumor size or stage of the disease (Table 3).

Clinical Course

A major postoperative complication developed in 41 of 88 patients for an overall morbidity rate of 47% (Table 4). A major complication occurred in 22 of 50 patients (44%) with adenocarcinoma of the head of the pancreas and in 19 of 38 patients (50%) with adenocarcinoma of the ampulla, distal bile duct, and duodenum. Among the 68 patients in whom a partial pancreatic resection was performed, a significant complication developed in 35 (51%), whereas a major postoperative complication occurred in seven of 20 patients (35%) managed by total pancreatectomy ($p > 0.05$). A significant postoperative complication developed in 36 of 74 patients (49%) in whom a partial gastric resection was performed and in five of 14 patients (36%) who had a pyloric-sparing Whipple procedure.

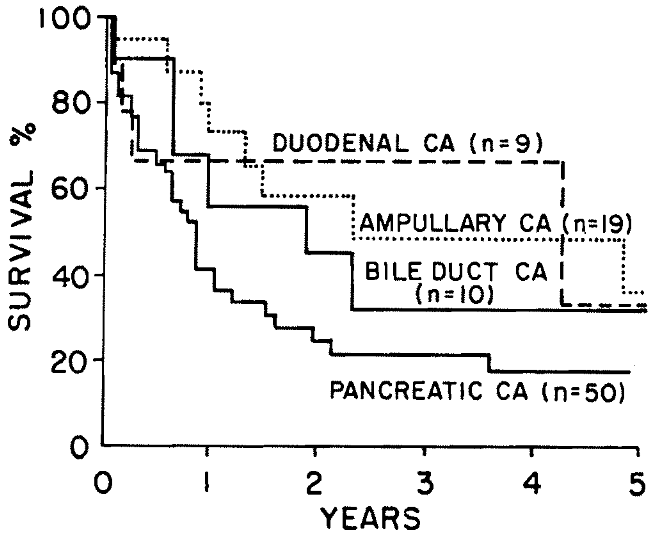

FIG. 1. Actuarial 5-year survival after Whipple resection for patients with adenocarcinoma of the pancreas, ampulla of Vater, distal bile duct, and duodenum.

A pancreatic fistula, defined as the persistent drainage of 50 mL or more of amylase-rich fluid per day for more than 2 weeks, developed in 12 of 68 patients (18%) who had a partial pancreatectomy. Eleven of these 12 fistulas closed spontaneously. One patient required reoperation 2 years after pancreaticoduodenectomy for a persistent fistula. Sepsis occurred in 17 of 88 patients (19%). In eight patients, the septic episode was related to the presence of an intra-abdominal abscess. Septic thrombophlebitis or central line sepsis occurred in five patients, urosepsis occurred in three patients, and cholangitis occurred in one patient. Wound infection occurred in 12 of 88 patients (14%).

An intra-abdominal abscess developed in nine of 88 patients (10%), requiring reoperation or percutaneous drainage. An intra-abdominal abscess occurred in six of 68 patients (9%) in whom a partial pancreatic resection was performed and in three of 20 patients (15%) managed by total pancreatectomy ($p > 0.05$). The presence of an underlying pancreatic fistula did not correlate with the subsequent development of either a wound infection or an intra-abdominal abscess.

Upper gastrointestinal bleeding developed in nine of 88 patients (10%). Bleeding occurred in five of 43 patients (12%) in whom a vagotomy was performed and in four of 45 patients (9%) managed without a vagotomy. One of 14 patients (7%) who had a pyloric-preserving Whipple procedure and eight of 74 patients (11%) in whom a partial gastric resection was performed had upper gastrointestinal bleeding ($p > 0.05$). Postoperative intra-abdominal hemorrhage requiring reoperation occurred in six of 88 patients (7%). Six patients required emergency re-exploration: one on the day of the initial operation, four on the first postoperative day, and one on the second postoperative day.

Temporary gastric outlet obstruction requiring nasogastric decompression for greater than 10 days occurred in 25 of 88 patients (28%). Delayed gastric emptying occurred in 12 of 43 patients (28%) in whom a truncal vagotomy was performed and in 13 of 45 patients (29%) managed without a vagotomy. Four of 14 patients (29%) who had a pyloric-preserving Whipple procedure and 21 of 74 patients (28%) in whom a partial gastric resection was performed had delayed gastric emptying.

In comparing the two periods, a significant decrease in the overall operative morbidity was observed during the more recent time period (Table 4). The overall morbidity rate was 36% among the patients operated on between 1981 and 1986 and 59% for those operated on between 1969 and 1980 ($p < 0.05$). During the recent period, there was a decreased incidence of many individual complications. However, analysis of the individual complications revealed a statistically significant decrease only with the complications of intra-abdominal abscess and sepsis.

There were 11 postoperative deaths among the 88 patients for an overall hospital mortality rate of 12.5% (Table 4). Four (36%) of the 11 patients died of sepsis and multisystem failure on the 26th, 49th, 60th, and 87th postoperative days. None of these deaths was due to a pancreatic fistula. Two deaths were associated with massive postoperative intra-abdominal hemorrhage requiring re-exploration for control of the bleeding source. Both patients died on the 3rd postoperative day of renal failure and respiratory insufficiency. Two patients died of pneumonia and respiratory failure on the 31st and 48th postoperative days. Two additional patients died of a sudden cardiac arrest on the 7th and 33rd postoperative days. Both of these deaths occurred in patients whose postoperative courses were otherwise unremarkable. The remaining patient died of acidosis and refractory hypotension on the 9th postoperative day. Postmortem examination revealed an infarcted right lobe of the liver, presumably as a consequence of ligation of an aberrant right hepatic artery arising from the superior mesenteric artery. During the recent period, a severe reduction in operative mortality has been observed. Ten deaths occurred during 1969–1980, whereas only one patient died in the recent period for hospital mortality rates of 24% and 2%, respectively ($p < 0.05$).

During the entire 18-year period, the actuarial 5-year survival rate was 18% for the 50 patients with adenocarcinoma of the pancreas (Fig. 1). The actuarial 5-year survival rate was 48% for the 13 patients with negative lymph nodes and 1% for the 37 patients with one or more positive lymph nodes ($p < 0.05$) (Fig. 2). There were no statistically significant differences in the sur-

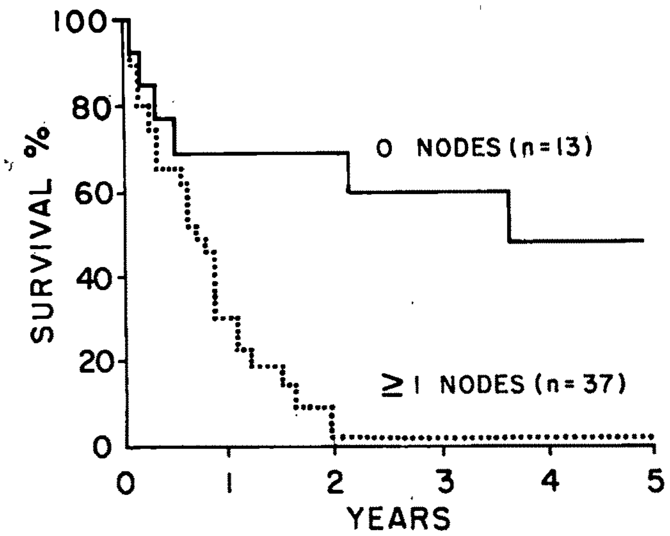

FIG. 2. Actuarial 5-year survival for those patients with adenocarcinoma of the pancreas with and without positive lymph node involvement.

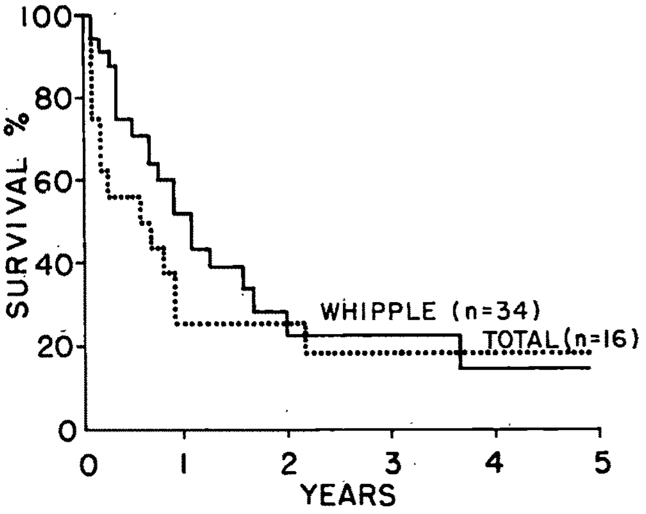

FIG. 3. Five-year actuarial survival for patients with adenocarcinoma of the pancreas managed either by total or partial pancreatectomy.

vival curves between the 34 patients with pancreatic cancer managed by partial pancreatectomy and the 16 patients with pancreatic cancer in whom a total pancreatectomy was performed (Fig. 3). The actuarial 5-year survival rate was 36% for patients with ampullary cancer, 34% for patients with distal bile duct cancer, and 33% for patients with cancer of the duodenum (Fig. 1). Among the 38 patients with nonpancreatic periampullary cancer, the 5-year actuarial survival rate was 23% for the 18 patients with positive lymph nodes and 40% for the 18 patients with no involved lymph nodes ($p = 0.29$).

In comparing the two periods, there were no significant differences in the 5-year survival rates for the 26 patients with adenocarcinoma of the pancreas operated on between 1969 and 1980 and for the 24 patients with pancreatic cancer operated on during the recent period (Fig. 4). Likewise, the 5-year survival rate was similar for the 15 patients with nonpancreatic periampullary cancer operated on during 1969–1980 and for the 23 patients operated on during the recent period.

Thirty-two of 50 patients with adenocarcinoma of the pancreas were operated on 5 or more years ago. Among these 32 patients, six have survived 5 years or longer. Of these six patients, four are alive at 60, 66, 72, and 132 months, respectively. One patient died 76 months after the Whipple resection of metastatic adenocarcinoma of the pancreas, whereas the remaining patient died at 66 months of unknown causes. In comparing the six long-term survivors with the 26 nonsurvivors, there was a trend toward a smaller tumor size among those surviving 5 years or more (2.7 cm *vs.* 3.2 cm, $p = 0.18$). In addition, positive lymph nodes were present in only one of the six (17%) 5-year survivors, whereas 22 of the 26 (85%) nonsurvivors had positive lymph nodes ($p < 0.05$).

Discussion

Over the past decade, a marked decline in hospital morbidity and mortality has been observed for patients undergoing pancreaticoduodenectomy. During the 1960s and 1970s, many centers[11–13] reported operative morbidity and mortality rates of 40–60% and 20–40%, respectively. However, a number of recent clinical re-

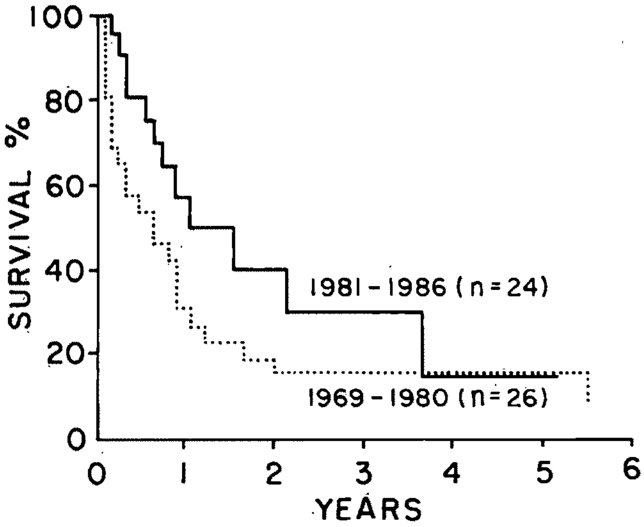

FIG. 4. Actuarial 5-year survival for patients with adenocarcinoma of the pancreas operated on between 1969 and 1980, and between 1981 and 1986. Survival at 5 years is similar for both groups of patients. The difference in survival during the earlier years is explained by the higher operative mortality during the earlier period.

ports[7-9] have documented an operative morbidity rate in the range of 30% and a hospital mortality rate of approximately 5%. A similar decline in hospital morbidity and mortality was noted in the current study. Among the 41 patients operated on during 1969–1980, hospital morbidity and mortality rates were 59% and 24%, respectively. In contrast, among the 47 patients operated on during the recent period, the perioperative morbidity and mortality rates fell to 36% and 2%, respectively.

The decline in operative morbidity and mortality observed during the recent period cannot be explained on the basis of a more select patient population, earlier diagnosis, or extent of disease at the time of operation. Comparison between the two periods revealed no significant differences between the two groups of patients in terms of mean age, race or sex distribution, associated medical illness, or preoperative nutritional status. Likewise, mean duration of symptoms and mean serum bilirubin levels at the time of presentation were similar for both groups of patients. Moreover, the stage of disease as assessed by mean tumor diameter and lymph node status were nearly identical for the two groups of patients.

In comparing the two periods, the number of Whipple resections performed each year at this institution for carcinoma of the head of the pancreas, ampulla, distal bile duct, and duodenum has increased from 3.4 operations per year to 7.8 operations per year. During this same period, a greater number of Whipple resections were performed by fewer surgeons. Between 1969 and 1980, 41 Whipple resections were performed by 22 different surgeons (1.9 operations/surgeon). During the recent period, however, the 47 Whipple procedures were performed by 14 different surgeons (3.6 operations/surgeon) with 50% of the resections performed by one individual. In addition, there has been a considerable change in the type of operation performed during the recent period. Between 1981 and 1986, there were fewer total pancreatectomies (9% *vs.* 39%) and fewer vagotomies (26% *vs.* 76%) performed compared with the earlier period. In addition, a pyloric-sparing Whipple procedure was performed in 14 of 47 patients (30%) operated on during the recent period, whereas a partial gastric resection was performed in all 41 patients operated on between 1969 and 1980. The fact that more operations were performed by fewer surgeons, and that a lesser operation was performed during the recent period, probably account for the shorter operative time (7.8 hours *vs.* 9.0 hours), the decreased mean intraoperative blood loss (1694 mL *vs.* 3271 mL), and the decreased transfusion requirement (3.6 units *vs.* 6.3 units) between 1981 and 1986. These findings suggest that the recent decline in operative morbidity and mortality may be due to fewer surgeons performing more Whipple resections in less time and with less blood loss.

Pancreatic fistula was a common complication in this series, and occurred in 12 of 68 patients (18%) in whom a partial pancreatic resection was performed. Fewer pancreatic fistulas developed during the recent period (14% *vs.* 22%), although this difference did not reach statistical significance. In contrast to other reports,[14,15] there were no deaths that could be directly attributed to the development of a pancreatic fistula in the current series. Neither did the presence of a fistula correlate with the presence of an intra-abdominal abscess, sepsis, or a wound infection. In addition, only one of 12 patients with a pancreatic fistula required reoperation for closure of the fistula at a later time.

Temporary delayed gastric emptying was the most common complication in this series and occurred in 25 of 88 patients (28%). The incidence of delayed gastric emptying was similar among those patients in whom a vagotomy was performed and in those managed without a vagotomy (28% *vs.* 29%). The incidence was also similar in those patients in whom a pyloric–sparing Whipple procedure was performed compared with those managed by a partial gastric resection (29% *vs.* 28%).

The actuarial 5-year survival rate for the 38 patients with nonpancreatic periampullary cancer was 34%. Although the 5-year survival rate (40%) was greater for those patients without lymph node metastases compared with those with nodal involvement (28%), this did not reach statistical significance. The 5-year survival rate for nonpancreatic periampullary cancer in this series was similar to the 30–40% 5-year survival rate reported by others,[15-17] but is less than the 58% 5-year survival rate reported by Grace and Associates[8] and the 70% 5-year survival rate in the series reported by Braasch and co-workers.[9] Surprisingly, the actuarial 5-year survival rate for the 50 patients in the current series with adenocarcinoma of the pancreas was 18%. Six of the 32 patients operated on 5 or more years ago have survived 5 years. Lymph node involvement was very important, with the 5-year actuarial survival rate being 48% in the absence of positive nodes and only 1% when lymph nodes were involved. There was also a trend toward improved survival with a smaller tumor mass. Both findings suggest that earlier diagnosis could have a great effect on overall survival for carcinoma of the pancreas. Of interest, however, is the finding that long-term survival is possible even in patients with positive lymph nodes. One of six long-term survivors with adenocarcinoma of the pancreas was found to have two positive lymph nodes in the resected specimen. This patient is currently alive 66 months after the Whipple resection. There was no difference in survival for those patients managed by total pancreatectomy when compared with those managed by partial pancreatectomy. The improvement in survival seen in this series was present throughout both periods, and a report from this institution[18] covering from 1959–1968, suggests that improved survival for pancreatic cancer was present then. To be certain that our six long-term survivors with pancreatic adenocarcinoma were not in fact patients with more favorable distal bile duct or ampullary lesions, all specimens were re-examined by a pathologist not involved in the original sign-out. All were confirmed as carcinoma of the head of the pancreas. A similar trend toward improved survival for patients with carcinoma of the head of the pancreas has also been noted by the GI Tumor Study group[10] and by Braasch and associates.[9] There is no obvious explanation for this observed improvement in survival for carcinoma of the head of the pancreas.

Survival in 1001 Patients with Carcinoma of the Pancreas

MARK M. CONNOLLY, M.D.,* PETER J. DAWSON, M.D., F.R.C.PATH,† FABRIZIO MICHELASSI, M.D.,*
A. R. MOOSSA, M.D., F.R.C.S.,*§ and FLORENCE LOWENSTEIN‡

From the Departments of Surgery, Pathology,† and the Registry of Neoplastic Diseases,‡ University of Chicago, Chicago, Illinois*

Among 1001 patients with carcinoma of the pancreas, 23 of 912 patients with exocrine carcinomas, 10 of 46 with ampullary carcinomas, and 21 of 43 with malignant islet cell tumors survived 3 years. Of the survivors with exocrine cancers, there were nine of 97 patients who had curative operation, two had had palliative resections only, and one was an incidental microfocal carcinoma; in the remaining 11 patients a histologic origin in the pancreas was not established. Preoperatively suspected and histologically proven 3-year survivors included six patients with ductal adenocarcinomas, three patients with mucinous cystadenocarcinomas, one patient with acinic cell carcinoma, and one patient with microadenocarcinoma. Only two patients can be considered cured. Tumor size and lymph node status did not correlate with survival. Cystadenocarcinomas comprised 1% of cases but one third of 3-year survivors. Long-term survival in histologically confirmed pancreatic carcinoma is a rare event that cannot be predicted in the individual case.

CARCINOMA OF THE PANCREAS is now fourth among the causes of death from cancer. Over the past 40 years, the incidence in the United States has tripled with an estimated 25,500 new cases in 1986.[1] The University of Chicago experience comprises 1001 cases that include cases of exocrine cancer, endocrine cancer, and carcinoma of the ampulla of Vater. Over 90% of cases are carcinomas of the exocrine pancreas, and it is here that the major problem resides. Although partial or total pancreatectomy may produce significant palliation, both in terms of prolonged survival and freedom from symptoms, there is some doubt as to the number of long-term cures that result. With this in mind, we have studied the records and histologic slides of patients who survived 3 years or longer after operation for exocrine pancreatic cancer at the University of Chicago Hospitals and Clinics between 1946 and 1983, to determine factors that may have influenced the favorable outcome.

Methods

A comprehensive list of all cases indexed as carcinoma originating from exocrine and endocrine pancreas as well as ampulla of Vater between 1946 and 1983 was obtained from the Registry of Neoplastic Diseases of the University of Chicago Hospitals and Clinics. Only patients who survived longer than 3 years were considered and the correctness of their pathologic diagnosis was verified. During this process the pathology of all cases operated for cure and all putative 3-year survivors was reviewed. Carcinomas originating from the endocrine pancreas as well as the ampulla of Vater are not considered in detail in this paper. The diagnosis of "ampullary carcinoma" was restricted to cases where the tumor clearly arose either in the wall of the ampulla or from adjacent duodenal mucosa. Such cases usually showed little or no invasion of the subjacent pancreas. We found that a number of cases originally considered to be carcinomas of the pancreas in reality arose in the ampulla.

Follow-up was available in all cases. Survival times were measured from the date of operation. With rare exceptions the study was confined to examination of the patients' records and review of existing slides, although in a few cases additional recuts and special stains were made. Our data on resectability rate, operative mortality, and long-term survival were compared with those reported in the English literature from 1945 to 1984.

Results

A total of 1001 patients with carcinoma of pancreas were seen at the University of Chicago Medical Center between 1946 and 1983. These included 43 patients with malignant islet cell tumors and 46 patients with carcinoma arising in the ampulla of Vater. There were 54 putative 3-year survivors, 21 with malignant islet cell tumors, 10 with carcinoma of the ampulla of Vater, and 23 with carcinoma of the pancreas. This paper reports in detail the findings in the latter group of patients, all of whom came from a subset of 766 cases of carcinoma of the pancreas that were treated primarily at our institution. The remaining 146 were initially staged elsewhere and were referred to us for adjuvant therapy. Eighty-nine patients with solid ductal carcinomas, six with cystadenocarcinomas, and one each with acinar cell carcinoma and microadenocarcinoma, respectively, had resection for cure. The extent of these operations is detailed in Table 1.

TABLE 1. *Cases of Carcinoma of the Exocrine Pancreas Operated on for Cure at the University of Chicago Hospitals and Clinics Among 766 Cases Diagnosed and Treated During 1946–1983**

	Solid Ductal Adenocarcinomas	Cystadenocarcinomas and Miscellaneous
Total pancreatectomy	39	1
Whipple	39	3
Distal pancreatectomy	11	4
Total	89	8

* This does not include two of the long-term survivors who were not operated on for cure.

In the larger group of solid ductal carcinomas, the resectability rate was 11.6%. The operative mortality rate was 23.1% for total pancreatectomy and 25.6% for pancreaticoduodenectomy. A total of 67 patients with ductal carcinomas survived the immediate postoperative period. In this group the mean survival was 16.9 months. In 58 patients, the lymph node status was available (this information was lacking in some earlier cases). There was essentially no difference in survival between patients with positive and negative nodes (18.4 *vs.* 17.2 months). In the smaller group of patients with cystadenocarcinomas, the resectability rate was 67%.

The search through the files of the Registry of Neoplastic Diseases yielded a total of 23 3-year survivors (Table 2). Of these, only 11 had a histologically confirmed primary carcinoma arising in the head, body, or tail, and only nine had been operated on for cure. Seven more patients had a histologic diagnosis of carcinoma after exploratory laparotomy and biopsy, but an origin in the pancreas could not be confirmed. In four additional patients there was a clinical diagnosis of pancreatic carcinoma, but histologic proof was lacking, and, in the last patient, a microfocal carcinoma was found incidentally.

The histologically proven survivors fell into two groups: one group comprised six patients with adenocarcinomas of ductal origin and a miscellaneous group comprised one patient with acinar cell carcinoma, one patient with microadenocarcinoma, and three patients with cystadenocarcinomas. The details of these patients are summarized in Table 3. All the adenocarcinomas occurred in older patients (58–72 years, mean: 67 years) with a predominance of females. All were located in the head of the pancreas and measured from 1 to 5.5 cm in diameter. Only the smallest tumor was confined to the head of the pancreas. In four cases, tumor extended into the wall of the duodenum and in two cases the duodenal mucosa was ulcerated. One tumor extended into peripancreatic fat. Histologically all were well-differentiated adenocarcinomas of ductal origin, and one was predominately mucoid. All showed lymphatic invasion, which was obviously perineural in five cases. Three patients had lymph node metastasis. One patient with negative nodes had obvious blood vessel invasion.

In contrast, the cystadenocarcinomas occurred in younger patients (39–54 years, mean: 45 years) and were located in either the head or tail. They tended to be large and ranged up to 21 cm in diameter. Histologically they were all well differentiated. All were mucinous, but two cases showed severe papillary infolding of the epithelium. The single acinar cell carcinoma extended into the wall of the duodenum and peripancreatic fat and had metastasized to seven nodes. The microadenocarcinoma was small and confined to the head of the pancreas, but both perineural lymphatic and blood vessel invasion were evident, and 4 of 21 nodes contained metastases.

The overall 3- and 5-year survival rates of the solid carcinomas were 6.7% (6/89) and 3.4% (3/89), respectively. All long-term survivors were operated on after 1960. Ultimately four of the six patients with ductal adenocarcinomas died of their disease. The two patients still alive without evidence of disease had tumors that measured 1 and 5 cm in diameters, respectively; both

TABLE 3. *Details of Patients with Pancreatic Carcinoma Surviving 3 Years or Longer*

Age/Sex, Diagnosis	Location and Size (cm)	Extent	Invasion Lymph Nodes	Treatment	Follow-up*
F/68, duct cell adenocarcinoma	Head 5.5 × 5.5 × 5.5	Duodenal wall and bile duct	L 3/20	Whipple, RT for recurrence	Died 6.5 years
F/58, duct cell adenocarcinoma	Head 1.0 × 1.0 × 1.0	Confined to pancreas	LP 0/23	Total pancreatectomy	Well 7.25 years
F/62, duct cell adenocarcinoma	Head 3.2 × 3.0 × 2.4	Muscularis of duodenum	LP 5/29	Bypass followed by total pancreatectomy	Died 3.5 years
F/72, duct cell adenocarcinoma	Head 4.0 × 2.3 × 1.6	Peripancreatic fat	LPV 0/15	Total pancreatectomy, postoperative RT and CT	Died 3.7 years
M/67, duct cell adenocarcinoma	Head and body 4.0 × 3.0 × 3.0	Ampulla and ulcerated duodenum	LP 4/44	Total pancreatectomy	Died 3.25 years
M/72, duct cell adenocarcinoma	Head 5 × 5 × 5	Ulcerated into duodenum	LP 0/20	Whipple	Well 12 years
F/54, mucinous cystadenocarcinoma	Tail 21 × 21 × 21	Metastases in ovary, colon, and stomach	— 0/1	Partial pancreatic cystectomy, Salpingo-oophorectomy, RT for recurrence†	Died 3.3 years
F/39, mucinous cystadenocarcinoma	Tail 17 × 17 × 17	Well circumscribed	— 0	Distal pancreatectomy	Recurrence at 14.5 years, died 16.25 years
M/42, mucinous cystadenocarcinoma	Head "Large"	Adherent to duodenum and celiac axis	— 0/1	Biopsy only†	Died 8.75 years
M/41, acinar cell carcinoma	Head 2 × 1.5 × 1	Peripancreatic tissues and duodenum	L 7/32	Total pancreatectomy, postoperative CT	Alive with recurrence 5.1 years
F/30, microadenocarcinoma	Head 2.7 × 2.5 × 1.9	Localized	LPV 4/21	Biopsy, preoperative RT, Whipple and intra-arterial CT	Recurrence 2 years, alive with disease 3.7 years

* All times from date of operation.

† Not considered to be operated for cure.

L = lymphatic, P = perineural, V = vascular, RT = radiation therapy, CT = chemotherapy.

specimens revealed perineural invasion, although in both the lymph nodes were negative. Three of five patients in the miscellaneous group died of their disease and the remaining two patients are alive, but with recurrent disease.

Discussion

Our resectability and mortality rates in the treatment of solid adenocarcinoma of the pancreas are similar to the cumulative experience reported in the English literature, although there is great variability from one series to the other (see Tables 4 and 5). Table 6 lists 5-year survival rates after curative resections for pancreatic ductal adenocarcinomas in recent series; these range from 0–26.7%. Only three series report a 5-year survival rate greater than 10%.[2–4] These favorable long-term survival rates are probably not indicative of progress in the treatment of this disease. Rather, in the study of Kellum et al.,[4] as the authors point out, they only resected "favorable" cases in which tumors measured less than 3 cm in diameter. Another factor that must be taken into account in considering published results is the accuracy of histologic diagnosis and the influence that inclusion of cases of ampullary carcinoma can have on overall survival figures. van Heerden[5] found that among six previously reported long-term survivors, review of the histology revealed that two patients, in reality, had chronic pancreatitis, and one had an islet cell tumor. In our own series (see Table 2) 17% of putative 3-year survivors did *not* have histologically proven carcinoma, and, in a further 29% with histologically proven carcinoma, a definite origin in the pancreas was not established. All of these patients lived 3 years without a resection for cure.

TABLE 4. *Resectability Rate for Solid Adenocarcinomas of the Pancreas Reported in the Literature*

Senior Author	Period	Patients Treated	Patients Resected	Resectability Rate (%)

* 11 patients had a radical distal pancreatectomy.

of cystadenocarcinomas is 5 times that of ductal carcinomas. The relatively good prognosis of cystadenocarcinoma is well established.[6,7]

A particularly discouraging feature of our results has been that two thirds of those few patients who survived 3 years, eventually died of their disease. Furthermore, 50% of living patients have recurrent disease. Thus, it appears that the realistic goal of operation must be limited to significantly increased survival, free of symptoms, while maintaining low mortality and morbidity rates. Recently, several series have appeared in which there were no operative deaths,[8,9] emphasizing that in practiced hands this procedure does not carry a risk disproportionate to the long-term gain. Wilson and Block[10] demonstrated that survival after curative resection is significantly lengthened compared with survival after palliative bypass or mere biopsy. Unfortunately, no significant progress in long-term survival has been achieved in four decades. The reasons generally advanced for the poor long-term survival include delay and difficulty in early diagnosis,[11] although the patients in our series who survived longer than 3 years were not generally remarkable for the small size of their tumors. The fact that only 11.6% of our patients could be operated on for cure is in no way different from the general experience.

The location of the pancreas at an anatomic crossroad with drainage to multiple lymph node basins makes a curable lesion an uncommon event. Therefore it is the relative balance of operative mortality *versus* the gain in short-term survival and quality of life that must be considered by each individual surgeon when operating on a patient with ductal adenocarcinoma of the pancreas. Appropriate resections, on the other hand, are clearly indicated for those small subsets of exocrine pancreatic cancers such as cystadenocarcinomas,[7] ampullary tumors,[12,13] and endocrine tumors.[14]

A poorly understood facet of the disease is that of the biologic potential of individual cancer, which appears to be the major factor determining prognosis.[15] In our series, two of 11 survivors were not operated on for cure, yet they survived 3.3 and 8.75 years, respectively. Recently, quantitative tumor DNA analysis has shown that DNA content correlates with the malignant potential of the individual tumor.[16] It remains to be seen if this information will be of clinical usefulness in tailoring the operative procedure for patients with pancreatic carcinoma.

This study underlines the dour prognosis for ductal carcinoma of the pancreas and emphasizes the need to

identify and appropriately treat those other pancreatic tumors whose biologic behavior offers a substantial chance for long-term survival after resection.

Acknowledgment

The continued support and advice of Dr. George E. Block is gratefully acknowledged.

DISCUSSION

DR. HARVEY R. BERNARD (Albany, New York): Data have been collected from all patients discharged from a New York hospital since 1980. Dr. Axelrod, Commissioner of Health for the State of New York, has authorized me to present data pertinent to the matters under discussion this morning.

(Slide) Three points deserve mention. One, these data relative to radical pancreaticoduodenectomy for cancer of the pancreas indicate no statewide improvement in mortality over the period of study.

(Slide) The data are similar in this regard relative to total pancreatectomy for cancer. There is no significant difference from year to year.

Two, practice improved performance. Those hospitals in which the operation was performed four times or more reported a significantly better mortality than did hospitals with less experience. The mortality rate was greater than 30% for hospitals with only one procedure per year. (Slide) Again, the data are similar for total pancreatectomy.

(Slide) This improvement is more clearly demonstrated by the data from 1985 both for the Whipple operation and for total pancreatectomy.

Three, these operations continue to be comparatively rare experiences for a surgeon. The most experienced surgeons in New York State reported only 10 operations: 6 Whipples and 4 total pancreatectomies in 1985.

The average general surgeon in New York State can expect to perform only 2–3 such operations in a 30-year surgical experience with the likelihood of a 30% mortality rate at the current writing.

These operations have been selected for discussion at an upcoming statewide New York Quality Insurance meeting as models of high-risk, high-morbidity, and low-yield procedures, which demonstrates that practice induces improvement.

We must ask ourselves: what are surgeons prepared to do about this?

DR. ANDREW L. WARSHAW (Boston, Massachusetts): I rise mainly to congratulate the authors of both these series and to try to resolve some of what I perceive as a possible conflict between these two papers, one of which is telling us that the Whipple operation is doing much better and the other is telling us how dismal the whole picture is. I believe both are correct and for different reasons.

In our hospital we have also seen a much improved picture, just as Dr. Cameron and Dr. Crist have reported. In my last 88 pancreaticoduodenectomies, including patients up to the age of 86, there have been no postoperative deaths. Nonetheless, if you consider the overall survival of all patients with pancreatic cancer, not just those who can be resected, the world literature shows a total survival rate of 0.4%. What that means is that most patients have metastatic cancer when we first see them. The conflict is therefore not in how we operate on the selected few with cancer in the head who can be resected, but on how we select those patients for operation.

Many patients do not have cancer in the head of the pancreas, and most do not have nonmetastatic disease. Can we stage them in advance, possibly to change approach or even to avoid an operation? In various European series, upwards of 50%, in some cases 75%, of all operations for pancreas cancer are laparotomy and biopsy. I would suggest that in this day and age that is unacceptable.

In our study of patients who apparently had cancer confined to the head of the pancreas, by all standard modalities including CT, angiography, and MRI, we still find that more than 40% have demonstrable gross metastases in the liver or on the peritoneal surfaces at the time of or before the proposed Whipple operation, as demonstrable by laparoscopy. Many of these metastases would undoubtedly have been missed at casual exploration. To my mind this emphasizes the importance of accurate preoperative staging.

In light of that observation, I would like to ask the authors what criteria they use for excluding patients for operation? Will you operate on all patients at any age, or can you identify medical factors that would exclude a patient? We used to exclude patients over 70, but that clearly is not true any more.

In the setting of the poor natural history when the operation is frankly palliative and there are known metastases, is there now a place for totally nonoperative management, such as either endoscopic or percutaneous stenting instead of a bypass? Do we have any evidence that stenting is either better or worse than operative bypass?

Finally, both authors have referred to the presence or absence of positive nodes. There are various reports that either say positive nodes make a difference or they do not. Is this simply the positive node that the pathologist tells you about afterwards, that you did not recognize at the operation, or if you saw grossly positive nodes or biopsy proven positive nodes, would that deter you from doing the Whipple operation? Is the operation so safe now that you would carry it out in obviously palliative circumstances?

DR. JON VAN HEERDEN (Rochester, Minnesota): The two papers just presented, I believe contain both good and bad news. The good news is that pancreatic resection can, in 1987, in experienced hands, be performed with an acceptably low operative mortality and morbidity. The bad news is that by and large, this low operative mortality has not enhanced long-term survival.

Today, at least 90% of patients with ductal adenocarcinoma remain nonresectable, and a 5-year survival rate above 5% is a rarity.

As eloquently outlined by our Chicago colleagues, it is vitally important that the histology of all long-term survivors be re-evaluated, perhaps by an independent pathologist.

The histologic differentiation between a ductal adenocarcinoma, fibrosing pancreatitis, and an islet cell tumor can be notoriously difficult. To our chagrin we found approximately 8 years ago that in a series of six patients who we reported as being 5-year survivors, on re-review three of the six patients did not have ductal cancer; two had pancreatitis and one had an islet cell tumor.

I urge all of us involved in this to have this independent histologic review for all patients who have survived for more than 3 years.

From Dr. Block and his colleagues, I would like to know whether the operative mortality in their experience has dropped in recent years. The operative mortality rate of 23% for total pancreatectomy and 25% for pancreaticoduodenectomy seem extraordinarily high. I wonder too how many surgeons are involved in pancreatic resection at your institution.

(Slide) During 1970–1985, 279 patients had the Whipple procedure at our institution. As you will see by this slide, we are performing an increasing number of Whipple operations, especially if you look at the last 3 years: 1983–1985. This occurs despite our rather conservative attitude towards performing pancreaticoduodenectomy.

We must, however, never lose sight of the overall perspective of patients with this disease entity. This was eloquently outlined by Dr. Connolly. If you look at one recent year at our institution, 1984, of 185 patients with ductal adenocarcinoma, one third never were operated on. Of those who were operated on, an additional 38% had biopsy or bypass alone. A very small percentage had resection.

We have not been able to duplicate the excellent long-term survival as reported by Dr. Braasch and Dr. Cameron.
